Section I. Introduction

Purpose of this document

This document was developed to provide shoreline planners and managers with a summary of current science and management recommendations to inform protection of ecological functions of marine riparian areas (defined in Section III). Washington Administrative Code (WAC 173-26-186(8)) directs that Shoreline Master Programs (SMPs) “include policies and regulations designed to achieve no net loss of those ecological functions.” The Washington State Department of Ecology has produced guidelines to help achieve this standard on marine shorelines of Washington (http://www.ecy.wa.gov/programs/sea/sma/guidelines/index.html). In addition, the state’s Aquatic Habitat Guidelines (AHG) program developed recommendations for protecting marine riparian functions: Protecting Nearshore Habitat and Function in Puget Sound: An interim Guide (2007) (http://wdfw.wa.gov/hab/nearshore_guidelines/). The AHG program is a partnership of state agencies dedicated to providing science guidance for protection of marine, freshwater, and riparian ecosystems. The AHG program develops guidance documents that can aid local governments updating Shoreline Master Programs (SMP) and Critical Areas Ordinances (CAO).

This information contained in this report will help inform local decisions regarding what is needed to protect ecological functions of marine riparian areas. Specifically, we summarize the range of marine riparian buffer widths (Appendix G) needed to meet particular levels of ecosystem function based on a literature review and input from an expert panel workshop.

Protection of marine riparian areas

Puget Sound’s marine shorelines and riparian areas have been altered over the last 160 years by human activities including agriculture, forestry and development. Nearly all of the merchantable timber along the marine shorelines of Puget Sound was harvested or burned by 1884 (Chasan, 1981). Although natural regeneration of riparian vegetation occurred in the years that followed, human manipulation of vegetation continues to influence marine shorelines today.

During the past three decades, an extensive body of research has emerged documenting the importance of riparian areas in providing ecological functions. These functions include:

- Water quality maintenance
- Fine sediment control
- Large woody debris (LWD) delivery and retention
- Microclimate moderation
- Nutrient delivery and retention
• Fish and wildlife habitat creation and maintenance
• Hydrology/slope stability

Most riparian research has focused on stream and riverine ecosystems. Attention to marine riparian processes and functions has only emerged in the literature during the past decade, and research in this area is increasing. Nevertheless, riparian areas provide ecological functions regardless of whether they are adjacent to freshwater or marine water bodies (Desbonnet et al. 1994, 1995; NRC 1996; NRC 2002; Brennan and Culverwell 2004).

Organization of document

In addition to the Introduction above, this document contains the following sections:
• Methodology used to compile information.
• Overview of marine riparian areas.
• Description of the seven most ecologically important riparian functions and recommendations for protecting (sustaining?) these functions.
• Impacts to riparian functions from activities associated with development, agriculture and forest practices.
• Recommendations to protect and sustain marine riparian functions.
Section II. Approach/Methods

This document summarizes our literature review and synthesis of scientific and technical information on riparian areas and presents recommendations to help protect marine riparian functions from common human activities. The following seven riparian functions are the focus of this document:

- Water quality
- Fine sediment control
- Shade/microclimate
- Large woody debris (LWD)
- Detritus and nutrients
- Fish and wildlife habitat
- Hydrology and slope stability

We addressed the following questions regarding the seven riparian functions listed above:

- What are the mechanisms or processes by which riparian areas perform each of the seven functions?
- How do human activities (i.e., agriculture, forestry, and development) affect riparian area function?
- What management approaches are most likely to protect each function?
- What data gaps and uncertainties exist relative to each function?

We paid particular attention to buffer-effectiveness research; that is, research focused specifically on the performance of buffers of varying widths at protecting riparian function for both freshwater and marine settings within and outside the Puget Sound region. We examined seven riparian buffer review documents to help determine the buffer widths that have been recommended to protect the seven riparian functions. These seven documents were selected because we identified them as being among the most thorough, frequently cited, and scientifically sound sources available (Appendix B). They were also selected because of their relevance to Washington State (Castelle et al. 1992; FEMAT 1993; Knutson and Naef 1997), the Puget Sound lowlands (Castelle et al. 1992; May 2000), and coastal systems (Desbonnet et al. 1994, 1995). Because some of the review documents did not consider wildlife, we added some pre 2000 references dealing with buffer recommendation for protection of wildlife that we encountered during the literature review.

We reviewed books, journals, online gray literature from government sites (USGS, US EPA, USDA, Washington State Departments of Ecology, Natural Resources, and Fish and Wildlife); online databases [Web of Science, CAB Abstracts, ProQuest, ScienceDirect, Agricola], and bibliographies [most notably one written by David Correll for the Smithsonian Institution, Correll 1999]. A summary of this information is contained in Appendix C, Tables 1-7.
In Appendix G, we summarized buffer width recommendations from Appendix C to achieve 80-100% effectiveness. We did this in three ways. First we report the smallest and largest buffer widths recommended in the literature that achieved a minimum of 80% effectiveness for that function. For example, the buffer width recommendation for the water quality function ranges from 5-600 m (16 -1920 ft) across all water quality studies.

Secondly, we present average values, which are based on the arithmetic mean of all buffer widths recommendations from the literature cited in Appendix C that achieve a minimum effectiveness of 80%. For example, the mean width to achieve a minimum of 80% effectiveness among 11 studies in appendix C for water quality function was 109 m (608 ft). For single studies that offer a range of buffer widths to achieve a minimum of 80% effectiveness, we took the average of that range before including it with data from other studies. For example, for the water quality function, Mayer et al (2006) offer a buffer range of 6-70 m (19 -224 ft) to achieve 91-99% effectiveness for subsurface flows for a grass forest buffer. We used a value of 38 m (122 ft, i.e., the average of 6 and 70 m; 19-224 ft) to represent this study.

Finally we provide buffer width recommendations to meet 80% effectiveness based solely on FEMAT curves. The FEMAT curves plot the relationship between the effectiveness of a mature forests buffer at providing an ecosystem function at various buffer widths. For example, the FEMAT curve for LWD indicates that an approximately 40 m (131 ft) buffer width achieves 80% effectiveness of the LWD function. In some cases, the FEMAT function curves illustrate several parameters e.g., the water quality FEMAT curve shows total suspended solids (TSS), sediment, nitrogen and phosphorus. In this case, a range of widths is reflected in the recommendations, to address each parameter of concern. FEMAT curves did not address hydrology/slope or wildlife functions. FEMAT (1993) uses site potential tree height (SPTH) as a proxy for buffer width where one SPTH = 61 meters (200 ft). FEMAT defines site potential tree as “a tree that has attained the average maximum height possible given site conditions where it occurs” (FEMAT 1993). Like other characteristics of Puget Sound marine shorelines, site conditions and thus site potential tree heights will vary across Puget Sound region.

We found no effectiveness studies for litter fall or hydrology/slope stability and thus do not report on this function in terms of buffer width effectiveness. For all other function, we report on the buffer widths that achieve 80% effectiveness as opposed to other values of effectiveness simply because most of the studies could be summarized at this level. The description of effectiveness at the 80% level does not imply a recommendation for adopting that level of effectiveness.

Because much of the literature was related to freshwater riparian systems, we assembled an interdisciplinary science panel to inform the process of adapting fresh water studies to marine nearshore environments (Marine Riparian Workshop Proceedings 2008; Appendix H ). We used FEMAT (1993) curves as a tool to communicate with the science panel. First developed in 1993 for freshwater environments, FEMAT curves depict the relationship between ecological functions and the width of mature riparian forests along a generalized shoreline. Relationships between ecological function and width of riparian zones for specific shorelines may differ from this generalized model due to site-specific factors such as slope, soil, geomorphology, plant community type, disturbances, anthropogenic alterations, etc. A riparian function curve for
wildlife was not developed due to the complexity of life history requirements for the wide variety of wildlife found in marine riparian areas, as well as the lack of scientific information on this topic.

The decision to adapt FEMAT-style curves for the marine environment was based on the assumption that studies used as the basis for developing these curves can be generally applied to the marine environment. The rationale for this application relates to the similarities of riparian functions between marine and fresh water systems and the support for this application from a number of publications (e.g., Desbonnet et al. 1994, 1995; NRC 2002; Brennan and Culverwell 2004) and the science panel.

The summary of literature reviews, buffer recommendations and adapted FEMAT curves were provided to the science panel at a workshop to solicit their opinion as to the applicability of the riparian function curves to the marine environment. The workshop was held on November 19, 2008 at the University of Washington. It included 14 scientists representing multiple disciplines relevant to riparian function and processes. A proceedings document entitled Draft Marine Riparian Review Technical Workshop Proceedings was produced as a result of this workshop and contains the names, affiliations and expertise of science panel members (Appendix H). The consensus of the science panel is that freshwater riparian buffer research as generally depicted in the FEMAT curves is applicable to the marine environment. Exceptions are noted in the workshop proceeding. The recommendations contained in this guidance document are the result of these efforts.
Section III. Overview: Riparian Areas and Riparian Buffers

**Riparian areas**
As defined by the National Research Council (NRC 2002):

Riparian areas are transitional between terrestrial and aquatic ecosystems and are distinguished by gradients in biophysical conditions, ecological processes and biota. They are areas through which surface and subsurface hydrology connect water bodies with their adjacent uplands. They include those portions of terrestrial ecosystems that influence exchanges of energy and matter with aquatic ecosystems (i.e., zone of influence). Riparian areas are adjacent to perennial, intermittent, and ephemeral streams, lakes, and estuarine–marine shorelines.

**Riparian buffers**
Riparian buffers are generally recognized as a “separation zone” between a water body and a land use activity (e.g., timber harvest, commercial or residential development) for the purposes of protecting ecological processes, structures, functions) and/or mitigating the threat of a coastal hazard on human infrastructures (National Wildlife Federation 2007). As used here, buffers are defined as separation zones (as above) that are relatively undisturbed by humans and thus represent mature vegetation consistent with the potential of the site.

**Why are marine riparian areas important?**
Based in large measure on our understanding of fresh water riparian ecosystems marine riparian areas likely play a central role in maintaining the health and integrity of aquatic and terrestrial ecosystems (Desbonnet et al 1994; NRC 2002; Brennan and Culverwell 2004). Many of the functions of freshwater riparian areas are similar to marine riparian areas, although marine riparian areas also provide functions that are unique to nearshore ecosystems due to differences in biogeochemical processes, ocean influences and differences in the biota between fresh and marine environments. Marine riparian areas provide a broad suite of functions, seven of which are the focus of this document. These include water quality (filtration and processing of contaminants); fine sediment control; inputs of large woody debris (LWD); shade/microclimate; litter fall/organic matter input; hydrology and slope stability; and fish and wildlife habitat (see Section IV). There are a number of other functions provided by marine riparian areas which were not reviewed nor discussed here e.g., recreation, cultural and aesthetic resources, carbon sequestration, and providing protection from threats of coastal hazards.
Section IV. Riparian Functions

1. Water quality

a. Technical overview: riparian influence on water quality function

Of the seven riparian functions addressed in this document, water quality is perhaps best understood. Riparian areas provide water quality benefits through a variety of mechanisms including:

- Infiltration and corresponding reduction of surface runoff rates/volumes;
- Intercepting nutrients, fine sediments and associated pollutants from surface water runoff;
- Binding dissolved pollutants with clay and humus particles in the soil;
- Conversion of excessive nutrients, pollution, and bacteria from surface and shallow groundwater into less harmful forms by riparian vegetation; and
- Regulating water temperature.

The water quality function of riparian areas is facilitated by vegetation and soils, which slow the flow of surface and subsurface water and increases retention or “treatment” time. Vegetation, geology, landform, and soil characteristics can affect the manner and rate at which water flows over and through the riparian area and the extent to which groundwater remains in contact with plant roots and soil particles (Klapproth and Johnson 2000). Microorganisms found in riparian soils and sediments, including bacteria, fungi, and other biota, are capable of metabolizing pesticides and transforming nutrients and other chemicals into less toxic forms (Ettema et al. 1999; Klapproth and Johnson 2000). They can also perform chemical reduction reactions such as denitrification (Adamus et al. 1991; Schoonover and Williard 2003; Rich and Myrold 2004). In addition to reducing the pollutant load to receiving waters, microorganisms cycle nutrients including carbon, nitrogen, and phosphorus. Soils high in very fine materials (e.g., clay) tend to be less permeable and may facilitate greater runoff, while sand-dominated soils can facilitate rapid draining and therefore limited sediment retention (Hawes and Smith 2005). Fine mineral soils or soils with high levels of aluminum or iron may be more likely to perform the nutrient removal/transformation function than other soil types (Adamus et al. 1991).

Trees, shrubs and herbaceous plants can trap and retain pollutants from the atmosphere, sediments, surface runoff and groundwater (Correll 1997). Plants also help lengthen the residence time of water by decreasing flow and velocity, which can increase filtration and soil retention potential (Evans et al. 1996; Klapproth and Johnson 2000; Ducros and Joyce 2003). Vegetation can help mediate nutrient and pollutant input into receiving waters by stabilizing banks to reduce erosion, storing runoff, trapping sediment, and transforming nutrients (Omernik et al. 1981; Smith 1992; Osborne and Kovacic 1993; Arthington et al. 1997).
b. Key findings from buffer literature and science panel on water quality

Numerous studies have investigated the role of riparian buffers composed of vegetation such as grass and forest in controlling the transport of sediment, nutrients, pesticides, metals, microorganisms, and other contaminants to receiving waters (NRC 2002). Most research focuses on nonpoint source pollution, particularly nutrients (phosphates/phosphorus, nitrates/nitrogen), TSS, and sediments. To a lesser degree, research has also addressed bacteria and other pathogens along with oils, pesticides, and herbicides. Appendix C, Table 1 provides a summary of water quality buffer recommendations reviewed for this document.

Our review suggests that:

- The range of buffer widths that met a minimum 80% effectiveness for this function was 5 – 600 m (16-1920 ft; Appendix G). This wide range relates to the breadth of water quality issues. See Appendix C to get more specific widths related to specific water quality parameters.
- Minimum buffer widths to achieve 80% effectiveness for different elements of water quality functions can be extrapolated from the literature and are listed in Appendix G.
- Site characteristics and the amount and nature of the contaminant in the water influence the buffer’s capacity to ameliorate those contaminants.

A riparian function curve for water quality was developed for review by the science panel to determine its application to the marine environment. Summary data from Desbonnet et al. (1995) (Table 1) were used to generate a series of curves for four commonly studied contaminants including sediment, TSS, nitrogen and phosphorus (Figure 1). These curves, which are similar to those developed by FEMAT (1993), demonstrate function (in terms of % removal of contaminant) based on a number of studies at different locations and under different site conditions. Note that curves are contaminant-specific despite similarity of shape.

Panelists generally agreed that the function curves are conceptually valid for water quality issues originating in marine riparian areas. However the panel distinguished marine riparian from freshwater riparian function on the basis of drainage area and relative contribution to Puget Sound water contamination. Relative to the dynamics affecting water quality in Puget Sound at the watershed and landscape scales, undisturbed marine riparian area’s contribution to maintaining water quality is limited to the area that drains directly into Puget Sound. Anthropogenic activities in marine riparian areas include the generation and routing (via water) of pathogens, nutrients, toxics, heat, and fine sediment (above normal background levels) that can affect water quality. However, the marine riparian area is limited in spatial extent; that is, it constitutes a small fraction of the Puget Sound drainage basin. Most contaminants reach Puget Sound via streams or drainage networks discharging into the Puget Sound Basin, or pathways
that concentrate rainfall and snowmelt from impervious surfaces associated with human residential and commercial development and transportation infrastructure. Washington State Department of Ecology, United States Environmental Protection Agency, Puget Sound Partnership Publication Number 07-10-079 (http://www.ecy.wa.gov/pubs/0710079.pdf); and waste water entering Puget Sound from municipal and industrial facilities. The panel did not address nutrient or pathogens from agricultural sources or residential septic systems.

Table 1. Summary data adapted from Desbonnet et al. (1994, 1995) used to generate generalized curve for removal effectiveness of various pollutants at different buffer widths. This data is identical to Desbonnet et al (1995) with the exception of the zero point which we added for illustrative purposes.

c. Conclusions and Recommendations for water quality

The literature review (see Appendix C) shows removal effectiveness as a function of buffer widths. In general, the larger the buffer, the greater its effectiveness in performing a water quality function. Long-term studies suggest that contaminant loading can increase over time (depending on the site conditions and type of contaminant), thereby reducing the overall effectiveness of the buffer.

This document focused on four major water quality contaminants that have received the most attention from researchers: nitrogen, phosphorous, total suspended solids and fine sediment. Soil characteristics, slope and vegetation cover type are the most important determinants of buffer effectiveness to protect water quality. To maximize the buffer’s effectiveness to remove contaminants, the following actions are recommended in order of priority:

- Retain, restore, or enhance vegetation, particularly native vegetation.
- Manage drainage to ensure that water is moving evenly through the buffer to maximize retention time and infiltration, rather than flowing through pipes, culverts, rills, or other conveyance mechanisms. Avoid routing drainage to adjacent streams that may transect marine riparian areas.
- Avoid the use of pollutants (petroleum, toxics, pesticides, etc) in or near riparian areas.
- Avoid construction of impervious surfaces and septic tank drain fields in riparian areas.
• Manage agricultural and pasture lands to minimally disturb buffers.
• Limit or prohibit the application of pesticides and herbicides in or near riparian areas.
• Avoid disturbance (e.g., grading, compaction, removal) of native soils.

2. Fine Sediment Control

a. Technical overview: riparian influence on fine sediment control function

Riparian areas can play an important role in controlling fine sediment transport into local water bodies (fine sediments include fine-grained particles such as silt, clay, sand, and mud particles). As described previously, fine sediment plays an important role in ameliorating the effect of toxic chemicals and excessive nutrients in water quality. Fine sediment also is important in maintaining soil characteristics necessary for the growth and maintenance of riparian vegetation. However, maintaining natural erosion and sediment transport processes is critical to maintaining Puget Sound beaches and much of the sediment nourishing these beaches originates in marine riparian areas. The delivery of sediment to marine beaches is facilitated by natural driving forces (wind and wave action, bluff saturation, leading to slope failures) and it is very important to maintain these natural sediment inputs. Thus, there is a need to distinguish between “normative” sedimentation rates in marine riparian areas as opposed to human-induced changes to sediment inputs.

Fine sediments originate from a number of terrestrial sources, both natural and anthropogenic, however, the focus of this section is fine sediments originating from development, forestry, and agriculture, which can increase fine sediment delivery beyond normative rates. As used here, normative rate refers to the rate of sediment delivery in riparian areas undisturbed by human activity. Fine sediments become exposed and subject to erosion as a result of vegetation removal, excavation and compaction of soils. Once sediments are suspended in surface water, they can be delivered through run-off to adjacent waterways unless they settle out or become trapped. Undisturbed soils and vegetation in riparian areas act in concert to reduce erosion and slow the transport of fine sediment by the following mechanisms (adapted from Greenway 1987; Gray and Leiser 1992; and Gray and Sotir 1996):

• Riparian vegetation intercepts rainfall energy, helping prevent soil compaction;
• Roots and soils help bind and restrain soil particles and increase sheer strength of the soil;
• Vegetation slows surface runoff allowing for increased localized sediment deposition and decreasing off-site transport;
• Porous and permeable soils improve water absorption reducing surface flow; and
• Transpiring vegetation helps moderate soil moisture levels, which increases infiltration and decreases saturation that leads to increased surface water run-off.
Riparian vegetation can play an even more significant role in sediment and erosion control in steep areas through mechanical reinforcement of sediment via roots and stems and by modifying hydrology through soil moisture extraction (Gray and Sotir 1996). Mature plant communities can be more effective in maintaining slope stability than immature communities. Benefits of vegetation increase in areas with several layers of vegetative cover such as herbaceous growth, shrubs, and trees (Menashe 2001).

**b. Key findings from buffer literature and science panel**

Most studies include fine sediment control as a component of the water quality function because many contaminants adhere to sediments and increasing inputs of sediments to water bodies can be considered a water quality problem. Appendix C, Table 1 provides a summary of fine sediment control buffer recommendations reviewed for this document.

Our review suggests that:

- The range of buffer widths that met a minimum 80% effectiveness for this function was 25-91 meters (Appendix G).
- Wider buffers are needed in areas with steep slopes.
- Site specific conditions should be considered when determining buffer width (e.g. soils, vegetation type and density, upland/adjacent land uses, and loading).

Two riparian function curves (one for sediment and one for TSS) were developed for review by the science panel (Figure 2) using summary data from Desbonnet et al. (1995) (Table 2). Note that these curves were included in the water quality section. The data were selected because Desbonnet et al’s (1995) work was one of the few sources of summary data for fine sediment control at various buffer widths, and represents a number of studies at different locations and site conditions. The data show that roughly 90 percent of sediment can be effectively removed by 30-60 meters (100-200 foot) buffers and roughly 90 percent of TSS can be effectively removed by 200 meter (650 foot) buffers.

There was general consensus by panelists that function curves for sediment control are conceptually valid. Panelists ranked the importance of this function relative to other marine riparian functions as low, largely because of the differences in effects of increased sediment inputs between freshwater and marine systems. Panelists noted that maintaining natural erosion and sediment transport processes is critical to maintaining Puget Sound beaches and much of the sediment nourishing these beaches originates in marine riparian areas. Further, they noted that delivery of this sediment is facilitated by natural driving forces (wind and wave action, bluff saturation, leading to slope failures) and it is very important to maintain these natural sediment inputs. Perhaps the biggest current threat to marine riparian systems from human activity is the reduction of sediment inputs by armoring shorelines and disrupting natural erosion of bluffs.
This is in contrast to freshwater systems, where riparian areas and roads are managed to minimize human-induced fine sediment inputs which can impact habitat and water quality of freshwater streams. Thus, the panel recognized the need to distinguish between “normative” sedimentation rates in marine riparian areas as opposed to human-induced changes to sediment inputs. Further, the panel recognized marine riparian areas should provide for “normative” sediment processes while reducing potentially harmful levels of fine sediments from anthropogenic activities.

**Table 2.** Summary data adapted from Desbonnet et al. (1994, 1995) used to generate generalized curve for removal effectiveness of various pollutants at different buffer widths. This data is identical to Desbonnet et al (1995) with the exception of the zero point which we added for illustrative purposes. Note that this table is identical to Table 1.

**Figure 2.** Sediment and total suspended sediment (TSS) removal effectiveness of two water quality parameters at various buffer widths (adapted from Desbonnet et al. 1995).
c. Conclusions and Recommendations for sediment

The literature reviewed for this document (see Appendix C) indicates a range of buffer width recommendations. In addition to buffer width, sediment transport through riparian areas is highly dependent on slope, land use, rainfall, and vegetation and soil type (Hawes and Smith 2005).

Based on the FEMAT-style figure presented in this section, to achieve 100% effectiveness of the buffer to control total suspended solids (TSS) requires a nearly 700 meter (2300 ft) buffer width, but will vary depending upon site specific conditions and fine sediment loading.

To maximize the buffer’s effectiveness to control sediment transport, the following actions are recommended:

- Maintain native vegetation cover.
- Minimize soil disturbance including compaction, plowing, grading and soil removal activities.
- Manage drainage and hydrologic conditions as described for other water quality functions.

3. Shade/Microclimate

a. Technical overview: riparian vegetation influence on shade function

Riparian areas can have microclimates that differ from upland areas and which influence physical and biological conditions at a local scale. Marine riparian areas are strongly influenced by marine water temperatures during both summer and winter months (warmer in the winter and cooler in the summer than upland areas). Living riparian (overstory trees, understory shrubs, and ground) vegetation, in turn, can intercept solar inputs and affect microclimate conditions such as soil and ambient air temperature, soil moisture, wind speeds, and humidity (FEMAT 1993; Knutson and Naef 1997; May 2003; Parkyn 2004). Terrestrial and aquatic microclimates are influenced by shade, and temperature fluctuations that can negatively impact both aquatic and terrestrial organisms, particularly those that can only survive within a relatively narrow range of temperature and moisture conditions.

Solar radiation has long been considered an important limiting factor for organisms in the upper intertidal zone of marine environments. Solar radiation affects distribution, abundance, and species composition (e.g., Ricketts and Calvin 1968; Connell 1972). Although research is limited, studies have quantified the influence of shade on marine organisms such as surf smelt (eggs) and talitrids (amphipods) on Puget Sound beaches. In their literature review of causes of spatial and temporal patterns in intertidal communities, Foster et al. (1986) found that desiccation is the most commonly reported factor responsible for setting the upper elevational limits of survival for intertidal animals. More recent studies (Pentilla 2001; Rice 2006) showed that a lack of shade on surf smelt spawning beaches results in higher temperatures, drier conditions, and increased egg mortality.
b. Key findings from buffer literature and science panel

Recommended buffer widths for the shade function in forested riparian areas include a range of values. Appendix C, Table 3 provides a summary of shade buffer recommendations that were derived from seven review documents and other literature.

Our review suggests that the range of buffer widths that met a minimum 80% effectiveness for this function was 17-38 meters (56 – 125 ft; Appendix G).

The FEMAT curve was selected to represent the shade function because it was the only data that depicted shade effectiveness as a continuous function of forested riparian buffer width. The values in Table 3 generally agree with values provided by other riparian review and synthesis reports. One method for comparing different recommendations among authors is to describe the buffer width at a given effectiveness level, such as 80%. For example, the FEMAT curve suggests approximately 80 percent effectiveness at about 37 meters. Other recommendations for achieving 80 percent effectiveness include Wenger (1999) (10-30 meters); Castelle et al. (1992): (30 meter minimum); May (2000): (30 meter minimum); and Knutson and Naef (1997) (11-46 meters to achieve 50-80 percent (Table 3).

Science panelists agreed that shade is an important function for a number of organisms in the upper intertidal areas during low tide (when exposed upper intertidal areas are subject to heating; see above). On the other hand shade in marine environments is potentially less important in moderating water temperature than shade in freshwater systems. Puget Sound water temperatures as a whole are unlikely to be affected much by shade cast by riparian vegetation, given the mass of water and the exchange rates with water from the Pacific Ocean, primarily through tidal actions. Further, shade from riparian areas is likely to cover only a small fraction of the upper intertidal area given the shallow gradients on many beaches and mudflats. Panelists noted that while increases in solar radiation due to loss of riparian shade could warm shallow intertidal waters, particularly pocket estuaries, the amount of warming and effects on biota have not been quantified.
Table 3. Data used to create generalized curve in Figure 3 indicating percent of riparian shade function occurring within varying distances from the edge of a forest stand (adapted from FEMAT 1993).

Figure 3. Generalized curve indicating percent effectiveness of riparian shade occurring within varying distances from the edge of a forest stand. Tree height (SPTH) is used to indicate buffer width where one SPTH = 61 meters (200 ft) (adapted from FEMAT 1993).

c. Conclusions and Recommendations

The literature review (see Appendix C) indicates a range of buffer width recommendations for protecting the shade function. Based on the FEMAT curve reported in this section of the report, approximately 1 SPTH (estimated at 61 meters or 200 ft) will provide nearly 100 percent
effectiveness of the buffer to protect the intertidal from desiccation, elevated temperatures, and other shade-related functions. Of course, in nonforested community types (e.g., prairie and grasslands) the shade function from overstory trees may be unattainable.

To maximize the buffer’s effectiveness to provide the shade function, the following actions are recommended:

- Avoid disturbance to native vegetation in riparian areas, especially nearer the water’s edge.
- Retain, restore, and enhance mature trees and a multi-layered canopy and understory of native vegetation at sites that support these types of plant communities.
- Ensure that riparian areas can be maintained in mature, native vegetation through time.
- Prevent modifications to banks and bluffs (e.g., armoring) that could disrupt natural processes (such as soil creep, development of backshore and overhanging vegetation, recruitment of wood and other organic matter to riparian area including beaches and banks.)
- Prohibit cutting and topping of trees and avoid “limbing” (selective branch cutting to enhance views) of trees for view corridors and other purposes within buffers.

4. Large Woody Debris

a. Technical overview: riparian influence on large woody debris function

Forested riparian areas are a significant source of large woody debris (LWD) in freshwater systems (Harmon et al. 1986; Sedell et al. 1988; Bilby and Bisson 1998; Hyatt and Naiman 2001). In marine environments, LWD (also known as ‘driftwood’) originates from both freshwater and marine riparian sources. Marine riparian areas contribute LWD to shorelines through natural recruitment processes, including windstorms, fires, wave action, and landslides (NRC 1996). Most of Puget Sound’s bluffs are naturally unstable and landslides are a common occurrence throughout the region (Johannessen and MacLennan 2007).

Large woody debris provides numerous benefits to shorelines and riparian areas including:

- Moderation of local water temperature and soil moisture;
- Accumulation of detritus serving as a food source and habitat for invertebrates;
- Support of terrestrial vegetation (such as nurse logs);
- Structural complexity that provides habitat for fish and wildlife;
- Sediment trapping and bank erosion control.

Recent research in the Puget Sound region has shown that marine LWD serves similar functions including provision of structural complexity; moderation of local water and soil temperatures; and habitat creation. An overview of the marine research by topic area follows.

LWD and Substrate Temperature: Several studies conducted in Puget Sound have shown that LWD has a significant effect on substrate temperatures (Higgins et al. 2005; Rice 2006; Tonnes
For example, in a study conducted in north Puget Sound, Tonnes (2008) found that mean sediment surface temperatures under LWD on accretionary beaches were 7.7°C cooler than beach sediments lacking LWD. Mean surface temperatures under driftwood on bluff-backed beaches were 2.4°C cooler than nearby sediment. LWD influences sediment temperatures below the surface. Mean temperatures were cooler at depths of 5 centimeters and 15 centimeters under LWD on both accretionary and bluff-backed beaches (Tonnes 2008).

**Detritus:** Driftwood accumulates detritus from both marine and upland sources, which is consumed by invertebrates, birds and other organisms (Polis and Hurd 1996; Pank 1997; Dugan et al. 2003; Rodil et al 2008).

**Invertebrate biomass:** Detritus entrained in driftwood has been linked with increased invertebrate biomass which, in turn, supports higher level prey for species such as shorebirds. Amphipods (Talitridae) are the most abundant macroinvertebrate on Puget Sound beaches. In a study of north Puget Sound beaches, Tonnes (2008) found that amphipods represent the predominant biomass of invertebrates within the supratidal zone (e.g. within driftwood). Amphipods are strongly associated with driftwood, where they find refuge from predators, favorable temperature and moisture conditions, and organic matter for consumption. Higher densities of amphipods have been found associated with wood than bare sediment.

**Structural support:** Marine LWD also provides structural support for vegetation similar to nurse logs in upland settings. In a survey of >1 meter (3.28 ft) diameter wood along 3.9 kilometers (2.3 miles) of Puget Sound beaches, Tonnes (2008) found that 71 percent supported at least one species of terrestrial vegetation. In addition, large wood supported a mean of 2.4 species of vegetation with up to 11 species on a single log. Backshore areas can be relatively dry, exposed and nutrient deficient, and driftwood may play an important role in providing structural stability, moisture and nutrients for establishment of other plant species.

**Habitat:** Increased vegetation provided by driftwood also increases primary productivity and increases structural complexity for fish and wildlife. May et al. (1997) found wood to be one of the most important factor in determining habitat for salmonids in fresh water systems. Driftwood embedded in beach berms and/or at the toe of banks helps dissipate wave energy and retain sediments that, collectively, act to buffer the effects of storm waves and longshore currents by moderating or reducing bank erosion. It also provides potential roosting, nesting, refuge and foraging opportunities for wildlife; foraging, refuge and spawning substrate for fish; and foraging refuge, spawning attachment substrate for aquatic invertebrates and algae.

**b. Key findings from buffer literature and science panel**

Numerous studies have investigated the role of riparian areas in providing LWD to adjacent water bodies. Appendix C, Table 4 provides a summary of LWD buffer recommendations that
were derived from seven review documents and other research. Most studies find that LWD originates from within one site potential tree height of the riparian area, although steeper slopes may provide LWD from greater distances. Establishing appropriate buffers to maintain the LWD function must therefore account for processes affecting the potential for the land-water interface to change through time such as sea level rise.

A number of studies and reviews of riparian buffers note that, in addition to considering the benefits of LWD in adjacent water bodies, it is important to consider LWD benefits within the terrestrial environment, specifically for its contribution of ecological functions e.g., nurse logs, habitat, nutrient recycling, and helping maintain soil moisture. Appendix C, Table 1 provides a summary of fine sediment control buffer recommendations reviewed for this document.

Our review suggests that:

- The range of buffer widths that met a minimum 80% effectiveness for this function was 17-38 meters (Appendix G).
- Buffer width effectiveness is strongly influenced by site conditions (such as slope) and potential height of mature trees.

The curve adapted from FEMAT (1993) (Appendix D) generally agree with values provided by other riparian review and synthesis reports. The FEMAT curve reveals approximately 80% effectiveness at about 40 meters; the science panel generally agreed that the curve is conceptually valid.

Figure 4. Generalized curve indicating percent effectiveness of LWD recruitment from riparian areas occurring within varying distances from the edge of a forest stand. Tree height (SPTH) is used to indicate buffer width. One SPTH = 61 meters (200 ft) (adapted from FEMAT 1993).
c. Conclusion and Recommendations
The literature reviewed for this document (see Appendix C) indicates a range of buffer width recommendations for protecting the LWD function. Buffer width effectiveness is strongly influenced by site conditions (such as slope, vegetation type and age structure, and natural disturbance regimes).

There are a range of buffer widths for achieving high levels of effectiveness based on the literature in Appendix C ranging from 10 to 130 m (33 – 427 ft). The FEMAT (1993) riparian function curve indicates 100 percent effectiveness of the LWD function at approximately 60 meters (200 ft).

To maximize the buffer’s effectiveness to provide the LWD function, the following actions are recommended:

- Avoid human disturbance in riparian areas.
- Allow for the accrual of drift wood and other upland sources of LWD on beaches and shorelines.
- Protect, restore, and enhance marine riparian trees to help ensure a long-term source of LWD.
- Provide buffers that allow for long-term source and recruitment of trees (LWD) as shorelines retreat, or as a result of soil creep and landslides, and increasing sea levels.

5. Litter Fall/Organic Matter
a. Technical overview, riparian influence on litter fall/input of organic matter
Riparian vegetation provides litter that serves as habitat and food for fishes and aquatic invertebrates (Adamus et al. 1991; Levings and Jamieson 2001; Vigil 2003; Lavelle et al. 2005) and influences the amount and type of terrestrial invertebrates that fall into aquatic systems. Terrestrial invertebrates serve as a major food source for fishes (including salmon) birds, mammals, reptiles, and amphibians. Terrestrial insects have recently been shown to be a large component of the diet of juvenile salmonids residing in nearshore waters of Puget Sound. In addition, some fish and invertebrates feed directly on vegetative detritus (McClain et al. 1998; King County DNR 2001; NRC 2002; Vigil 2003; Brennan et al. 2004; Lavelle et al. 2005; Fresh 2007; Duffy et al in review). Nutrient exchange occurs in two directions from the terrestrial to aquatic systems and vice versa. Examples of nutrient-energy exchange (marine to terrestrial and terrestrial to marine) include:

1. Atmospheric input via wet or dry deposition, which can occur through fires, intensive farming and agricultural activities, and wind erosion (Lavelle et al. 2005).
2. Lateral transfers of nutrients through tidal and wave action, including microalgae and macroalgae washed ashore (Adamus et al. 1991).
3. Decomposing secondary consumers, such as juvenile Pacific herring, Pacific sand lance, longfin smelt, surf smelt, sole, salmon, seabirds, and marine mammals, which also contribute nutrients. For example, Pacific salmon nutrients are deposited by predators and scavengers in excreta, or as carcasses and skeletons (Cederholm et al. 1999; Naiman et al. 2002; Drake et al. 2006).

4. Secondary consumers can transport nutrients to upland areas, facilitating nutrient and energy exchange between terrestrial and aquatic food webs (Ballinger and Lake 2006). For example, Elliott et al. (2003) examined the relationship between bald eagles and Plainfish Midshipman, a demersal fish and intertidal spawner. Between May and June of 2001, the authors found that eagles consumed about $22,700 \pm 3,400$ midshipman, representing large transfers of nitrogen into upland areas, and the potential to enhance community productivity along the shoreline.

**b. Key findings from buffer literature and science panel**

A number of references identify the contributions of organic matter (e.g., forest litter, terrestrial insects, woody debris) and food web linkages between freshwater and marine riparian areas and adjacent water bodies (Appendix C, Table 5). Most studies conclude that the delivery of leaf and other organic matter declines at greater distances away from the water’s edge, and that most contributions are made within 30-60 meters (100-200 ft) of the shoreline. Appendix C, Table 5 provides a summary of litter fall buffer recommendations that were derived from seven review documents and other research.

Our review suggests that:

- The range of buffer widths that met a minimum 80% effectiveness for this function was 17-38 meters (Appendix G).
- Most litter contributions are made within 30-60 meters (100-200 ft) of the shoreline.
- As in fresh water riparian systems, the delivery of leaf and other organic matter delivered to the marine intertidal areas declines with distance away from the water’s edge.

A riparian function curve for litter fall was adapted from the original FEMAT curve (Appendix D). The FEMAT curve reveals approximately 80 percent effectiveness at about 25 meters. The science panel generally accepted that the litter fall curve is a valid representation of marine riparian environments. Panelists also generally agreed that riparian areas are likely to produce insects that fall into the adjacent waters.
Table 5. Approximated values for cumulative effectiveness of buffer width for litter fall/organic matter inputs used to create Figure 5, based on the original FEMAT curve.

**Figure 5.** Effectiveness of riparian litter fall/organic matter input as a function of distances from the water’s edge (adapted from FEMAT 1993) where one site potential tree height is approximately 60 meters or 200 ft.
c. Conclusion and Recommendations for litter fall/organic matter inputs

The literature reviewed for this document (see Appendix C) indicates a range of buffer widths to achieve this function. In addition, the function curve derived from FEMAT indicates that approximately 100 percent of the litter fall function is achieved at 60 meter (200 ft).

To maximize the riparian function for litter fall/organic matter inputs the following actions are recommended:

- Maintain native riparian vegetation in the riparian area.
- Avoid human disturbance to vegetation.
- Allow for natural succession of plant communities and maintain sources and accumulations of organic matter within riparian areas and on beaches.

6. Hydrology/Slope Stability

a. Technical overview: riparian influence on hydrology/slope stability function

The role of vegetation in protecting hydrologic processes and slope stability is well documented. The information generally falls into two areas: research focusing on the impacts of sediment inputs to streams and wetlands; and research focused on protecting human infrastructure from anthropogenic disturbances such as logging, agriculture and development.

Sidle et al. (1985) found that tree and shrub root strength contributes to slope stability, and loss of root strength following tree death or removal may lead to increased incidence of erosion and slides. Vegetation also helps lengthen the residence time of soil moisture by decreasing runoff volume and velocity. This in turn can increase filtration and soil retention potential (Evans et al. 1996; Klapproth and Johnson 2000; Ducros and Joyce 2003) and slope stability (Williams and Thom 2001).

Vegetation plays an important role in affecting hydrologic processes and slope stability in the following ways (adapted from Gray and Leiser 1982):

- **Interception**: Foliage and plant litter absorb the energy of precipitation, reducing direct impacts on soil.
- **Restraint**: Root systems bind soil particles and blocks of soils, and filter sediment out of runoff.
- **Retardation**: Plants and litter increase surface roughness, and reduce runoff volume and velocity, thereby reducing channelization.
- **Infiltration**: Roots and plant litter help maintain soil porosity and permeability.
- **Transpiration**: Plants absorb moisture, delaying the onset of soil saturation and surface runoff.
**Root Reinforcement:** Roots mechanically reinforce soil by transferring shear stresses in the soil to tensile resistance in the roots.

**Soil Moisture Depletion:** Interception of raindrops by foliage and evapotranspiration limit buildup of soil moisture.

**Buttressing and Arching:** Tree trunks can act as buttress piles or arch abutments in a slope, counteracting shear stresses.

**Surcharge:** The weight of vegetation on a slope may exert a destabilizing down slope stress and a stress component perpendicular to the slope that increases resistance to sliding.

**Root wedging:** Roots invade cracks and fissures in soil or rock that could add restraint stability or cause local instability by wedging action.

**Wind throw:** Strong winds cause trees to blow down that can disturb slope soils

Soil saturation strongly influences erosion potential on a slope. The more water that can be intercepted, absorbed, or otherwise controlled by vegetation, the greater the slope stability. Soil composition and slope geometry (slope height and angle) are also major factors determining slope stability. Studies have shown that decreasing vegetation cover results in increased soil saturation and slope failure during rainfall events. Some slope failures are unrelated to vegetation cover, usually as a result of unusually high precipitation, undercutting, strong winds, or other factors. However, in studies of slope failures in urbanized areas such as Seattle, over 80 percent of slope failures were attributed to human influence such as vegetation removal and poor drainage management (Tubbs 1975; Laprade et al. 2000).

**b. Key findings from buffer literature and science panel**

None of the buffer research reviewed for this paper provided buffer recommendations for maintaining slope stability and natural hydrologic processes see Appendix C, Table 6). However, two documents include some analysis that could be helpful in determining buffer widths to protect hydrologic functions. Knutson and Naef (1997) include relevant discussion regarding erosion control. Additionally, FEMAT (1993) identified the relationship of tree root strength to slope stability and provides a generalized effectiveness curve for root strength.

Since a riparian function curve for hydrology and slope stability was not found in the literature, data from Griggs et al 1992 as cited in Macdonald and Witek (1994) were used to describe setbacks on bluffs or other unstable slopes to protect against property loss. The minimum setbacks for different bluff heights and various levels of stability are illustrated in Table 6 and Figure 6. These setbacks do not account for ecological functions but rather focus solely on protection against property loss. The FEMAT curve developed for this function is estimated based on extent of root systems adjacent to a slide scar margin, or “soil stabilizing zone of influence” (equal to slide scar width plus half a tree crown diameter). Such information is not easily interpreted into a buffer width or under the variable site conditions existing on marine
shorelines. It appears that neither FEMAT (1993) nor other literature makes buffer recommendations. Much of the shoreline in Puget Sound is composed of bluff-backed beaches, which are naturally eroding. Buffers should be based on site-specific slope conditions, with steeper slopes having wider buffers. This approach is similar to establishing stream buffers from the outside edge of the 100-year floodplain. However, the variability and multitude of factors that need to be considered in determining slope stability in the marine shoreline make it difficult to develop specific buffer width recommendations for this function. We offer information from Griggs et al 1992 as a way of conceptualizing the idea of maintaining riparian function on unstable slopes.

All science panel members agreed that the hydrology/slope stability curve developed with data from Griggs et al. 1992 as cited in Macdonald and Witek (1994) is applicable in the marine environment. Panelists discussed the importance of hydrology, geomorphology, soil type, and vegetation type in supporting slope stability functions in Puget Sound, in addition to the human safety concerns about slope stability in the region.

**Geomorphology**

- Landforms and geology can be more important here than buffer width. For example, in the San Juan Islands, there can be a 45° slope on basalt form that can be very stable.
- Geomorphic shore form is an important consideration – geologic legacy, landscape position, density, slope, etc. Use of Shipman (2008) geomorphic classification system may be useful (Appendix F).

**Soil and Vegetation**

- Riparian areas can increase slope stability (through root structure) and increase water interception and absorption. Protecting natural rates of sediment delivery and protecting processes and functions of nearshore ecosystems may be achieved by establishing and maintaining adequate riparian buffers.
- Upslope alterations can be contributing factors to slope instability.
- It is important to consider flow paths; for example, slope stability may be associated more with altered upland drainage patterns or precipitation patterns. Buffer width versus landform may be the most important factor. For example, steeper slopes, particularly those with underlying geologic instability, require wider buffers.
Table 6. Setback distances (in ft) from Griggs et al 1992 as cited in Macdonald and Witek (1994) for different bluff heights at various levels of stability where geologic stability for 50-years cannot be demonstrated.

Figure 6. Construction setbacks for different bluff heights at various levels of stability, where geologic stability for 50-years cannot be demonstrated (after Griggs et al 1992 as cited in Macdonald and Witek 1994).
c. Conclusion and Recommendations
No riparian function curve was developed for this section, due to the high variability of site specific conditions that may be encountered and the lack of summary data that could be generally applied.

To maximize the buffer’s effectiveness to maintain hydrologic functions and slope stability, the following actions are recommended:

- Avoid development near naturally eroding bluffs.
- Avoid engineering approaches that encroach on buffers to create more stable slope conditions.
- Avoid impervious surfaces and compacted soils.
- Maintain riparian vegetation especially on steep slopes to prevent excessive erosion and allow for evapotranspiration.
- Avoid ‘loading’ of bluffs whereby excessive moisture (from irrigation, septic fields, impervious surfaces, and other sources of water) can exacerbate the instability and erosion potential of the site.

7. Fish and Wildlife Habitat
a. Technical overview, riparian influence on wildlife function
Provision of wildlife habitat has been well documented for freshwater riparian systems (e.g., Knutson and Naef 1997; Cederholm et al 2000; NRC 2002, Buchanan et al. 2001). Riparian areas provide the resources and structure to meet important life history requirements such as feeding, roosting, breeding, refuge, migration corridors and clean water for a variety of wildlife species. Knutson and Naef (1997) report that riparian areas contribute to the high productivity and species diversity in aquatic and upland areas.

The wildlife function of marine riparian areas is not well documented, although Buchanan et al. (2001) Brennan and Culverwell (2004) described a wide variety of fish and wildlife associations for marine riparian areas of Puget Sound. Wildlife species have adapted to the natural processes, structure, and functions of marine riparian areas and have also played an important role in shaping the structure and character of riparian areas. For example, many birds and mammals that breed and rear in upland areas forage in intertidal areas. Thus, these species provide marine derived nutrients to uplands in the form of feces and carcasses. These marine derived nutrients play an important role in forest ecosystem health (Cederholm et al 2000).
b. Key findings from buffer literature and science panel

A number of studies have examined the role of riparian buffers in supporting wildlife. All studies reviewed for this document report that marine riparian areas function as important wildlife habitat. Appendix C, Table 7 provides a summary of wildlife buffer recommendations that were derived from seven review documents and other research.

Our review suggests that buffer requirements for fish and wildlife depend on different species’ individual habitat requirements and may be influenced by season, upland habitat quality and connectivity with other habitat areas.

The science panel generally agreed that marine riparian areas provide habitat for many wildlife species. Some participants pointed out that without buffers, numerous species would not utilize marine nearshore areas or cross onto beaches from upland areas. Perhaps more importantly, riparian buffers and other nearby relatively undisturbed areas provide habitat for riparian obligates (i.e., those that require habitat in close proximity to water bodies such as great blue heron). All panel members agreed that marine riparian areas provide a suite of important services for wildlife. Pertinent information from that discussion follows.

**Obligate/Optimal Use Species:** The science panel was uncertain if obligate species in Puget Sound’s marine riparian areas had been identified (but see Buchanan et al. 2001). They suggested that most wildlife in marine riparian areas are probably generalists in their habitat use, and the marine riparian environment supports a number of important functions and processes that create and maintain wildlife habitat. Larger buffers would increase the number of wildlife species using the area and benefit animals with larger home ranges.

**Invasive species** within riparian areas may reduce buffer effectiveness. Buffers can harbor nuisance wildlife species which is a cause for concern with respect to local wildlife and human populations.

c. Conclusion and Recommendations

The literature (see Appendix C) provides a range of buffer width recommendations, although few report 100 percent effectiveness. Relative to the other riparian functions discussed in this guidance document, wildlife needs are widely variable.

The ability to recommend a buffer width that would provide 100 percent effectiveness for wildlife is limited at this time because inventories of marine riparian wildlife species and their habitat requirements are lacking. Based on the literature surveyed for this guidance document, a buffer width greater than 200 meters (660 ft) will protect some wildlife habitat functions. Buffer requirements for fish and wildlife depend on the species’ individual requirements and these may change or be influenced by season, upland habitat quality and connectivity with other habitat.
areas. To maximize the buffer’s effectiveness to support wildlife, the following actions are recommended:

- Ensure that wildlife habitat connectivity is maximized through maintenance of riparian corridors.

- Ensure native vegetation diversity is maintained (both species composition and age structure) along buffers to offer maximum habitat opportunities to the broadest range of species.

- Allow for natural disturbances such as floods, wind throw and landslides to provide snags, LWD and other complex habitat structural features in the buffer.

- Understand which local species use marine riparian areas by consulting with WDFW Priority Habitat and Species lists or other sources so that buffers can be designed with those species’ habitat needs in mind.

Section V. Impacts to Marine Riparian Functions

1. Introduction

Riparian and aquatic ecosystems are currently being altered, impacted, or destroyed at a greater rate than at any time in history (Good et al. 1998). Although no comprehensive study has been conducted to document the rate and extent of marine riparian loss across the Puget Sound basin over time, three studies conducted between 1980 and 2006 provide some perspective on the region’s riparian losses. Bortelson et al. (1980 in Levings and Thom 1994) studied eleven major river deltas in Washington and documented a 76 percent loss in tidal marshes and riparian habitat during the preceding century. The major losses were within highly developed estuaries including the Puyallup and Duwamish River deltas (Bortelson et al. 1980 in Levings and Thom 1994). In 1995, scientists with the Puget Sound Assessment and Monitoring Program (PSAMP) found that approximately 33 percent (or 800 miles) of Puget Sound shoreline had been physically altered by bulkheads, docks, or other structures. These structures typically impact riparian areas through vegetation removal, soil removal and compaction. MacLennan and Johannessen (2008) conducted geographically-focused research in the San Juan Islands and found an average 25% loss of marine riparian forest cover on San Juan, Orcas, Lopez and Stuart islands between 1977 and 2006.

Impacts to riparian function from activities associated with development, agriculture and forestry are well documented in the literature and are summarized in Appendix E, Tables 1-2. As described in Section IV, the level of disturbance to riparian soils and vegetation are key factors determining riparian function. A more detailed description of each of these activities and its impact on riparian function is included in the next three sections.
2. Development

Modern development along marine shorelines usually involves the removal of native vegetation, topsoil and organic matter and the compaction of soils which result from clearing and grading, construction of buildings, pavement, and roads. Additional impacts include the introduction of nonnative plant species associated with landscaping. Loss of natural vegetation in riparian and stream habitats in developed areas is usually permanent, (Booth 1991 in Knutson and Naef 1997) and activities associated with development impact all riparian functions (See Appendix E, Tables 1-2). Thus riparian areas are more highly altered in developed landscapes than in agricultural and forested landscapes on a per acre basis (Booth 1991 in Everest and Reeves 2006) although agriculture and forestry typically occur over a larger proportion of the landscape than develop areas do. Below we provide a summary of literature addressing development activities and their impacts on riparian function.

a. Water quality

Development activities within riparian areas can affect water quality. Alteration within the riparian areas causes “changes in loading of nutrients, organic matter, and sediments (Valiela et al. 1992; Wahl et al. 1997; Jones et al. 2000; Jordan et al. 2003); increased loading of contaminants and pathogens (Siewicki 1997; Inglis and Kross 2000; Mallin et al. 2000); and changes in water flow (Hopkinson and Vallino 1995; Jones et al. 2000)” (in Hale et al. 2004). The shoreline and upland development of residential, business, and industrial facilities and utilities can result in altered topography, removal of vegetation, soil compaction and grading, and rerouting of surface and groundwater flows (Knutson and Naef 1997; NRC 2002; Ekness and Randhir 2007; Schiff and Benoit 2007). In general, habitat alteration and development creates impervious surfaces, which prevents water from infiltrating into the ground and thus the ability of soil to intercept toxic substances; increases the volume of surface water; increases the magnitude of local flooding (Montgomery et al. 2000 in Johannessen and MacLennan 2007); and increases flooding potential (Glasoe and Christy 2005).

b. Fine sediment control

Development impacts to the fine sediment/erosion control function of riparian areas are well documented. Concentration/channelization of surface runoff can lead to increased soil erosion along and downslope of the path of concentrated flow. Clearing of land for development produces the largest amount of sediment to aquatic resources (U.S. EPA 1993 in Stanley et al. 2005), and developed areas can produce 50-100 times more sediment than agricultural areas (Jones and Gordon 2000 in Stanley et al. 2005) on a per acre basis. Direct alteration of soils and vegetation within riparian areas can change nutrient loading rates, amounts and types of organic matter, and sediment dynamics (Valiela et al. 1992; Wahl et al. 1997; Jones et al. 2000; Jordan et al. 2003 in Hale et al. 2004). In sloped areas, these activities can also result in higher frequencies of slope failure, a relationship demonstrated through many field and laboratory studies (Gray and Sotir 1996; OSB 2007). Permanent loss of vegetative cover increases soil saturation and surface
water runoff, causing increased loading of fine sediments. While undisturbed mature native vegetation on slopes provides erosion control and slope stabilization benefits, disturbed or degraded sites can undergo continual erosion, which may hinder the development of effective vegetation cover. Competition by invasive, exotic plants, such as Himalayan blackberry, can also retard or preclude natural establishment of “effective” vegetation (Menashe 2001).

c. Shade/microclimate

The shade function of riparian areas is affected by many activities in the riparian area, particularly those occurring near the water’s edge. Vegetation removal can decrease shade (Macdonald et al. 1994; Thom et al. 1994; Macdonald 1995; Penttila 1996; Williams and Thom 2001) and increase water and beach substrate temperatures (Beschta et al. 1987; Williams and Thom 2001; Bereitschaft 2007). Rice (2006) and Sobocinski et al. (2003) demonstrated that shoreline modifications (such as boat ramps, bulkheads, roads, and parking lots) that involve vegetation removal close to the water’s edge not only reduce shade but also lower species diversity and abundance. Maintaining native vegetation in the form of mature trees in riparian areas can provide more shade than low-lying shrubs and grasses. Decreased shade, via removal of trees can result in increased egg mortality of beach-spawning forage fishes (Pentilla 2001; Rice 2006) and reductions in diversity and abundance of invertebrate species, as well as loss of habitat structure that supports climate sensitive species (Sobocinski et al. 2003; Brennan and Culverwell 2004; Tonnes 2008).

d. Large Woody Debris (LWD)

The reduced supply of LWD to nearshore ecosystems from marine riparian areas is largely the result of historic activities; however, impacts from ongoing development activities also affect this riparian function. Activities linked to development that affect marine LWD provision include tree removal for development within riparian areas (including shoreline armoring); wood removal (e.g., for fire fuel, landscaping, artwork, furniture); controlled and uncontrolled beach fires; salvage logging; drift log removal from open water; and vegetation removal.

Shoreline armoring can reduce or eliminate the upper intertidal and supratidal zones. This is turn may mobilize LWD and prevent it from settling on the shore. Low levels of LWD have been found on armored beaches compared to unaltered beaches (Sobocinski et al. 2003; Higgins et al. 2005; Dugan and Hubbard 2006; Defeo et al. 2009). Changes in wood abundance and elevated beach temperatures have been documented in several studies around Puget Sound (Higgins et al. 2005; Rice 2006; Tonnes 2008).

e. Litter fall/organic matter inputs

Alteration of riparian habitats can cause changes in nutrient loading, organic matter, and sediments (Valiela et al. 1992; Wahl et al. 1997; Jones et al. 2000; Jordan et al. 2003 in Hale et al. 2004). In freshwater systems, dams and other water control structures have caused changes in
nutrient cycling (Knutson and Naef 1997) through vegetation removal and soil compaction. Studies in marine systems show lower levels of terrestrially derived organic litter on armored versus unarmored beaches (Sobocinski et al. 2003; Higgins et al 2005; Dugan and Hubbard 2006; Defeo et al. 2009).

f. Wildlife
Shoreline modifications can have direct and indirect impacts on wildlife including interfering with species behavior, lowering survival, and decreasing habitat quality and quantity.

Habitat Loss/Quality
Shoreline modifications result in habitat loss, reduction, and or alteration (Paulson 1992; Levings and Thom 1994; Williams and Thom 2001; Toft et al. 2004), lower bird biodiversity (Donnelley and Marzluff 2004), altered food webs and benthic community composition (Dauer et al. 2000; Lerberg et al. 2000 in Hale et al. 2004), creation of passage barriers for salmon and other aquatic species (Williams and Thom 2001), and fragmented habitat (Williams and Thom 2001). The installation of shoreline armoring structures reduces beach width (decreases habitat), and can impede wildlife migration through shoreline corridors (NRC 2002). A reduction in habitat can lower diversity and abundance of wildlife, especially in upper intertidal areas. This can in turn cause change trophic relationships (Sobocinski et al. 2003; Defeo et al. 2009); for example, changes in the nearshore habitat can reduce potential spawning grounds for surf smelt and sand lance, which are a main component of the Pacific salmon diet (Johannessen and MacLennan 2007), and a primary food source for marine bird and marine mammals.

e. Hydrology/Slope Stability
Impacts to the hydrology/slope stability function of marine riparian areas have been widely documented in Puget Sound. Urbanization often causes compaction or removal of top soil, reducing infiltration and soil storage and increasing runoff. Erosion may increase downslope of concentrated flow outlet (e.g., pipe outfalls, impervious surface runoff) and may increase slope failure when this flow discharges to the top of the slope. Vegetation is a critical component in maintaining stable slopes (Morgan and Rickson 1995 in Parker and Hamilton 1999; Menashe 1993), and trees above the top of the slope contribute significantly to the geotectonic stability of the slope below (Parker and Hamilton 1999). Tree roots often anchor thin layers of soil to the bedrock or provide lateral stability through intertwined roots (Sidle et al. 1985 and Chatwin et al. 1994 in Stanley et al. 2005). In addition, changes to hydrology from the installation of onshore and offshore modifications affects sediment conditions.

3. Agriculture
Agriculture practices like other land use activities can result in the removal of riparian vegetation, addition of pesticides, soil disturbance and thus altered riparian functions. Many riparian areas became disconnected from the aquatic environment when tidelands and
wetlands/salt marshes were diked and filled to create farmland. In addition, agricultural sources of bacterial contamination, fertilizers and pesticides can threaten local water quality.

**a. Water Quality**

Water quality problems associated with agricultural activities include fecal coliform pollution, higher water temperatures, and nutrient and pesticide loading from surface and groundwater flows (Hashim and Bresler 2005). In some cases, excessive fertilizer use has led to increased nutrient levels in aquatic environments, causing algal blooms and eutrophication (Caffrey et al. 2007). Studies in the Puget Sound region show that agricultural activities can increase phosphorus levels in soils and surface runoff (Carpenter et al. 1998 in Stanley et al. 2005) and contribute 40 times the amount of nitrogen than forested areas and twice the nitrogen levels of developed areas (Ebbert et al. 2000 in Stanley et al. 2005). Agricultural activities that occur within, or drain to, riparian areas can negatively impact riparian soils and sediments by causing soil loss and erosion (Hashim and Bresler 2005), reductions in native vegetation (Spence et al. 1996), and altered flow paths leading to increased sediment, nutrient, pathogen, and pesticide loading (Sedell and Froggatt 1984). In addition, studies have shown that the conversion of riparian areas to cropland has decreased the infiltration potential of riparian soils (NRC 2002).

**b. Fine sediment control**

Agricultural activities can negatively affect the soil and sediment stability of marine riparian areas. Agricultural activities along Puget Sound shorelines typically result in a loss of native vegetation close to the water’s edge because the land is valued for crop production. This loss of vegetative cover and root structure can increase erosion rates into receiving waters (Sedell and Froggatt 1984).

**c. Shade/Microclimate**

Removal of trees within marine riparian areas reduces the amount of shade available (Hashim and Bresler 2005). Shade and temperature influence photosynthesis rates of plants and metabolic rates of animals. Fluctuations in temperature can alter fish community structure and composition (Baltz et al. 1987; Dambacher 1991; Hillman 1991; Reeves et al. 1987). High water temperatures can cause behavioral changes in fish by affecting migration timing and patterns (Spence et al. 1996).

**d. Large Woody Debris**

Agricultural activities within riparian areas have resulted in a loss of native vegetation and large woody debris, bank instability, and loss of flood-plain function (Spence et al. 1996).
e. Litter fall/organic matter inputs
Agricultural practices have impaired nutrient regulation in riparian areas. For example, the conversion of riparian areas to cropland has decreased the infiltration potential of riparian soils (NRC 2002), and agricultural activities often require vegetation removal (Everest and Reeves 2006). Excessive fertilizer use has led to increased nutrient levels in aquatic environments, causing algal blooms and eutrophication (Caffrey et al. 2007).

f. Hydrology/slope stability
Land clearing, tillage, wetland drainage, irrigation and grazing can lead to increased surface runoff and greater sediment delivery. Changes in hydrology as a result of agricultural activities can result in altered flow regimes, increased sedimentation, and modified and consolidated stream channels (Sedell and Froggatt 1984), as well as bank instability (Spence et al. 1996). Permanent loss of vegetation cover, or replacement by monocrops or other non-native vegetation increases soil saturation and surface water runoff. While undisturbed mature native vegetation on slopes provides erosion control and slope stabilization benefits, disturbed sites (such as tilled or over-grazed land) can undergo continual erosion, and may not establish an effective cover. Competition by invasive, exotic plants such as Himalayan blackberry can also retard or preclude natural establishment of effective riparian vegetation (Menashe 2001).

g. Wildlife
Agricultural activities within riparian zones have simplified aquatic and riparian habitats (Spence et al. 1996) and may result in lower biodiversity within these areas. Grazing practices in riparian areas can damage aquatic habitat through shoreline erosion, disturbance (when large animals disrupt stream channels and pools), and deposition of excess nutrients and fecal coliform.

4. Forest Practices
Coniferous forests are the dominant forest type throughout the Puget Sound basin, with the exception of areas with relatively frequent natural disturbance (e.g., landslides, wind stress), or soils that would not support conifers (e.g., rocky headlands, shallow soils). The age structure, density, diversity, and connectivity of existing riparian forests are important characteristics that determine the types and level of functions provided.

a. Water Quality
Industrial forest practices, including the use of fertilizers and pesticides, timber harvesting, and road construction and maintenance, can degrade water quality and cause changes in hydrology and riparian vegetation (Jones et al. 2000). Forestry activities within riparian areas negatively affect that area’s ability to perform its water quality functions in much the same way that
agricultural practices do. Specifically, the removal of riparian vegetation may limit the ability of riparian areas to decrease flows and filter, break down, and slow the flow of pollutants. Pesticides can be transported to riparian areas via surface and groundwater flows.

b. Shade/Microclimate
The removal of canopy through logging and thinning practices opens the understory and ground to increased light and air flow. The resulting microclimate changes can change the character of the plant species, expose soils and beach sediment to desiccation, and/or alter the temperature of water bodies below through the removal of shade-inducing foliage. Timber harvesting within riparian areas reduces shade and can increase water temperatures (Hashim and Bresler 2005).

c. Large Woody Debris
Large old-growth trees within marine riparian areas were historically among the first harvested in the region because of their close proximity to water and low transport costs (Prasse 2006; Brennan 2007; Chiang and Reese undated). Along Puget Sound shorelines and rivers, the number, size and species composition of trees has changed dramatically since the mid 1800s due to tree harvest, levee construction, development and invasive species colonization (Spence et al. 1996; Collins et al. 2002; Brennan 2007). As a result, the composition and volume of LWD on beaches has changed, with larger, mature logs occurring with less frequency. In a survey of 3.9 kilometers of beaches in north Puget Sound, fewer than 5 percent of large logs documented were considered ‘new’ recruits to the beach. The remaining 95 percent were severely weathered, and carbon dating revealed that many were delivered to the aquatic environment between 1700 and 1920 (Tonnes 2008).

The amount of new wood, especially large logs, delivered to beaches appears to be declining (Gonor et al. 1988; Maser and Sedell 1994; MacLennan 2005; Tonnes 2008). Old growth logs are decomposing and gradually disappearing from beaches. In addition, much of the wood currently being recruited to beaches consists of end-cut logs, which are more mobile (due to their smaller size and lack of a root wad and branches) and therefore provide somewhat different functions over shorter temporal and spatial scales (Tonnes 2008).

e. Fine sediment control
Road construction in forested areas increases sedimentation and reduces bank stability (Everest and Reeves 2006). Construction and maintenance activities can increase fine sediment loads and mass wasting processes (e.g., debris avalanches, debris flow, and debris torrents), which in turn can cause erosion and changes in stream channel (or beach) morphology (Hashim and Bresler 2005; Everest and Reeves 2006). Logging and burning can destabilize soils, increase the frequency and magnitude of erosion, and cause sedimentation (Knutson and Naef 1997).
f. Wildlife
Forest composition, structure and age class strongly influence type of wildlife habitat available and the diversity of wildlife that utilize the habitat. Old-growth rain forests of the Olympic Peninsula are among the most productive ecosystems in the world (Franklin and Dryness 1973), while younger second and third-growth forests provide fewer habitats and harbor a fewer numbers of species (Ruggiero et al 1991). Removal of forest cover and associated structure (such as snags and downed logs) can lower the habitat quality in riparian areas, reduce the input of nutrients into waterways (an essential food source for aquatic invertebrates) and eliminate important wildlife migration corridors.

Forestry practices can cause changes in the abundance and diversity of wildlife in riparian areas. This occurs through the loss of LWD, canopy and shrub cover, interior forest habitat within and adjacent to the riparian zone, sedimentation of the aquatic habitat, and habitat fragmentation (Knutson and Naef 1997).

g. Hydrology/Slope stability
Intact coniferous forests provide a perennial canopy and extensive root structure, which intercepts substantial amounts of precipitation, moderates surface and subsurface flows, and reduces erosion potential. Removal of forest cover and structure changes the character of the surface flow, particularly on steeper slopes where surface run-off accelerates and erosion and flash-flooding of small streams can occur.

5. Other Impacts of Concern
Development, agriculture and forest practices are only three of numerous potential impacts to riparian ecosystems. Additional impacts that were outside the scope of this guidance document include:

- Atmospheric deposition of pollutants.
- Harmful Algal Blooms (HABs) and other marine-borne pathogens and diseases.
- Non-native/nuisance Species.
- Recreation (harvest/collection of organism, trampling, wildlife disturbance).
- Climate change (changes in air/ocean temperature, sea level rise, changes in hydrology, and erosion from increased wave action, shoreline retreat, inundation, flooding).
- Oil and fuel spills from commercial shipping and tanker traffic.
Section VI. General Conclusions and Management Recommendations for Protecting Marine Riparian Function

This section is divided into four categories: (1) general conclusions adapted solely from the NRC (2002); and (2) broad, landscape-scale recommendations, (3) buffer width recommendations, and (4) impact-specific recommendations adapted from the literature review with input by the science panel as described above. These recommendations are intended to offer guidelines and approaches for protecting marine riparian functions addressed in this guidance document.

1. General Conclusions Adapted Solely from the NRC (2002)

- Riparian areas perform important hydrologic, geomorphic, and biological functions. These areas encompass complex above- and below-ground habitats created by the convergence of biophysical processes in the transition zone between aquatic and terrestrial ecosystems.
- Riparian areas cannot be thought of in isolation from associated water bodies. The characteristic geomorphology, plant communities, and associated aquatic and wildlife species of riparian and marine systems are intrinsically linked.
- Natural riparian systems have adapted to specific disturbance regimes. Managing riparian areas without regard to their dynamic patterns and influences of adjacent water bodies ignores a fundamental aspect of how these systems function.
- Riparian areas, in proportion to their area within a watershed, perform more biologically productive functions than do uplands. Riparian areas provide a wide range of functions, such as microclimate modification and shade, bank stabilization and modification of sediment processes, contributions of organic matter and large wood to aquatic systems, nutrient retention and cycling, wildlife habitat, and general food web support for a wide range of aquatic and terrestrial organisms.
- Riparian areas are effective in filtering and transforming materials (such as dissolved and particulate nonpoint source pollutants) from hill slope runoff.
- Because riparian areas are located at the convergence of terrestrial and aquatic ecosystems, they are regional hot spots of biodiversity and often exhibit high rates of biological productivity in marked contrast to the larger landscape.
- During the last decade, a patchwork of federal, state, and local laws and programs has come to acknowledge the importance of riparian areas and to require or encourage special management to restore or protect their essential functions, although the degree of protection, the focus, and the spatial coverage of these laws and programs are highly variable among federal, state, and local levels.

2. Overarching Recommendations

This section contains general management recommendations that broadly address riparian areas.

- Protect marine riparian soils and vegetation – prevent damage to native riparian soils and vegetation, including clearing and grading, compaction, covering (paving) and removal.
- Restore damaged marine riparian habitat – restore vegetation, soil characteristics.
• Account for scale issues (temporal and spatial) when evaluating riparian condition, current functions and potential for future functions, and cumulative effects of alterations. The dynamic nature and connectivity of riparian areas and linkages between riparian and aquatic systems operate at multiple scales.

• Exclude all major sources of contamination from the riparian buffer, including construction, impervious surfaces, mining, septic system drain fields, agricultural activity, clear cutting and application of pesticides and herbicides.

• Manage riparian areas for the long-term. For many sites, substantial time, on the order of years to decades, will be required for vegetation to become fully functional (NRC 2002).

• Require additional structural setbacks (10-30 ft) landward of buffers will allow routine maintenance of structures without compromising buffer function integrity.

3. Recommendations to Avoid or Minimize Specific Impacts
The following recommendations are directed at protecting riparian functions from activities associated with development:

• Avoid vegetation removal on shorelines and bluffs. If vegetation must be removed, minimize the area and amount removed and locate the disturbed area as far from the water as possible. Minimize ground disturbance, removal of mature trees, and introduction of nonnative vegetation, especially invasive species such as English Ivy.

• Avoid locating impervious surfaces in riparian buffers. If impervious surfaces must be located in riparian areas, minimize footprint, and mitigate impacts through techniques including pervious surfaces such as pervious pavers and concrete; bioretention facilities such as rain gardens; green roofs, cisterns, etc. Promote infiltration and implement approved methods/designs for controlling rates of surface runoff and pollutant loading. Caution should be taken when designing and installing bioretention and other facilities that infiltrate water along slopes and bluffs so as to not increase the likelihood of mass failures or erosion.

• Avoid shoreline modification; maintain existing native vegetation, particularly at and near the land-water interface. If shoreline alterations must occur they should be done in a way that minimizes potential negative impacts to natural functions and should use the least intrusive methods including bioengineering or relocating structures where feasible and practicable. All adverse impacts should receive full compensatory mitigation to ensure no net loss of ecological functions.

• Remove invasive plant species from marine riparian areas; Purple Loosestrife, Himalayan blackberry, English Ivy and other invasive plants compete with native species, particularly in disturbed sites along marine bluffs and shorelines.

• Restore and replant marine riparian areas with native vegetation to improve the connectivity of upland and marine riparian habitat, and to restore functions that benefit the nearshore and beach ecosystems. Ensure that replanted marine riparian areas are properly maintained to improve plant survival.
- Avoid building in the riparian buffers. If building must occur, then minimize footprint, site disturbance and locate structures far enough back from the water’s edge to ensure maintenance of functional riparian areas.

- Avoid locating septic and waste water systems in the riparian area. If they must be located in the riparian area, then they should be designed, maintained, and operated in such a way that that human waste and nutrients are prevented from leaching into local water bodies.

- Avoid disturbance to native vegetation in the riparian area, especially near the water’s edge, with the goal of maintaining vegetation communities that are resilient to disturbance from surrounding land uses and able to regenerate with minimal human intervention; and to help ensure that nutrients, pathogens, toxics, and fine sediments associated with land-use practices are prevented from entering water bodies.

- Avoid land use practices in riparian areas that involve the use or generation of nutrients, pathogens, and toxics. Avoid salvage or removal of downed trees, LWD or snags in riparian areas and on beaches. Maintain complex, multi-aged riparian forest cover and wide buffers to allow natural recruitment of LWD over long time frames.

APPENDIX B. Brief descriptions of seven buffer review documents

FEMAT 1993
The Forest Ecosystem Management Assessment Team (FEMAT) was formed in 1993 with a directive to assess management options for managing federal lands within the range of the Northern Spotted Owl along the west coast of the United States. The forest plan presents buffer effectiveness curves that were created to represent the relationship between buffer width and ecosystem function.

Castelle et al. 1992
This report focuses on the role of wetland buffers and their effectiveness in protecting ecosystem functions, and was developed for Washington State agencies to consult when creating policies for wetland protection. The report contains a literature review, an agency survey of buffer requirements of areas throughout the United States, and a field study of buffers in King and Snohomish counties.

Knutson and Naef 1997
This review of fish and wildlife habitat requirements was written for the Washington Department of Fish and Wildlife. The authors review freshwater riparian habitat functions (e.g., vegetation, litter fall, large woody debris, water quality) and assess the vulnerabilities of riparian habitats to human activities. The report provides recommendations using riparian habitat area (RHA) widths.

May 2000
This report covers buffers as means of protection for riparian habitat functions for stream systems in Kitsap County. The author summarizes buffer-related research and pays special attention to the preservation of salmonid habitat, including riparian wetlands, and instream spawning and rearing areas.

Desbonnet et al. 1994, 1995
Both papers focus on the role of vegetated buffers in coastal areas and provide recommendations. These papers review the benefits of vegetated buffers, their effectiveness in protecting ecosystem functions, and the variables that affect buffer effectiveness, including possible impacts from human activities and land use.

Wenger 1999
The authors reviewed about 140 articles and books for guidelines on riparian buffers with regards to their width, extent, and composition. This review was created to provide guidelines for local officials and natural resource managers in Georgia.

<td>&gt;30 m (&gt;98 ft) for effective reduction</td>
<td>Soil type, hydrology (flow paths), and subsurface biogeochemistry (e.g., organic carbon supply, high nitrate inputs) influence nitrogen removal in subsurface flows. Surface flows primarily remove nitrogen effectively when buffers are wide enough and sufficiently vegetated to control erosion and filter particulate nitrogen forms. Vegetation type (e.g., grass, trees, etc.) influences interception potential; for example, grass buffers are better at trapping sediment, filtering sediment-borne nutrients, and reducing sheet flow.</td>

<td>Buffer effectiveness increases with buffer width. Slope and vegetation cover are most important factors for reducing water quality impacts. Buffers less than 15m (50 ft) are generally ineffective in protecting wetlands.</td>
</tr>
</tbody>
</table>

1Unlike some other authors, Knutson and Naef (1997) does not offer minimum buffer width recommendations based on individual functions, but instead recommend Riparian Habitat Area (RHA) widths based on stream type. Authors note that WDFW does not identify minimum (RHA) widths because minimal conditions do not offer adequate habitat to support healthy fish and wildlife in the long run.

¹Unlike some other authors, Knutson and Naef (1997) do not offer minimum buffer width recommendations based on individual functions, but instead recommend Riparian Habitat Area (RHA) widths based on stream type. Authors do not identify minimum (RHA) widths because minimal conditions do not offer adequate habitat to support healthy fish and wildlife in the long run.

### Riparian function impaired
- Clearing and grading/vegetation removal
- Construction of homes, buildings, roads/impervious surfaces
- Shoreline armoring (docks, bulkheads, etc.)
- Landscaping (non-native plants)
- Recreational activities (hiking, biking, beachcombing, etc.)

### Specific activities associated with land use category
- Riparian areas are more highly altered in developed landscapes than in agricultural and forested landscapes
- Direct alteration within the riparian area (vegetation removal/reduction, soil compaction, grading) causes changes in loading of nutrients, organic matter and sediments; reduces capacity of riparian area to filter/absorb pollutants; increases sediment loading
- Creation of impervious surfaces (e.g., parking lots, paved streets, sidewalks, roads), vegetation removal, and soil compaction cause surface water to increase in volume and magnitude. Increased runoff decreases the ability of soils and vegetation to infiltrate and intercept pollutants, increases flooding potential.
- Construction of boat landings, docks, and piers creates increased slopes, causing increased and concentrated water flows; construction of domestic, residential and industrial facilities and utilities in and near riparian areas can result in altered topography, removal of vegetation, and rerouting of surface and groundwater flows
- Construction close to the water’s edge (bulkheads, docks, etc.) reduce shade as well as species diversity and abundance
- Areas with high levels of impervious surface coverage (>50%) correlated with low macrobenthic diversity and abundances
- Vegetation removal causes decreased shade and increased temperatures
- Removal of vegetation cover also reduces LWD and canopy cover, which serve to dissipate flow energy and control temperature by shading
- Increases of light levels in the upper intertidal zone results in higher levels of mortality and dessication of insects, invertebrates, and the eggs of intertidal spawning fish like Pacific sand lance and surf smelt.
- Low levels of organic litter and LWD have been found on armored beaches
- Increased surface runoff of toxins

### Impact findings on function
- Toxins can affect wildlife through physiological and behavior changes,
- Other impacts include changes in water quality, shade/microclimate, LWD, litter fall, fine sediment control, wildlife, hydrology/slope stability.

### Literature cited
- Knutson and Naef 1997; Montgomery et al. 2000 (in Johannessen and MacLennan 2007); Glasoe and Christy 2005; Hashim and Bresler 2005; Ekness and Randhir 2007; Schiff and Benoit 2007

- Klapproth and Johnson 2000; Krebs and Bums 1977; Krebs and Valiela 1978; Moore et al. 1979
reduced density and species richness (in Adamus et al. 1991; Firehock and Doherty 1995 (in Klapproth and Johnson 2000); Hashim and Bresler 2005; PSAT 2007).

Vegetation is a critical component in maintaining stable slopes. Roots anchor thin layers of soil to the bedrock or provide lateral stability through intertwined roots.

Decreased wood abundance and elevated beach temperatures have been documented in several studies around Puget Sound. Higgens et al. 2005; Rice 2006; Tonnes 2008.

Low levels of LWD and organic litter have been found on armored beaches as compared with unaltered beaches. Sobocinski et al. 2003; Dugan and Hubbard 2006; Defeo et al. 2009.

Offshore structures (e.g., breakwaters, jetties) can cause increased deposition of beachwrack. Martin et al. 2005 in Defeo et al. 2009.

Shoreline modifications result in:
1. wildlife habitat loss, reduction, and or alteration
2. lowered bird biodiversity
3. altered food webs and benthic community composition
4. creation of passage barriers for salmon and fragmented habitat connectivity
5. lowered abundance of wildlife which can cause harm to upper trophic levels, like Pacific salmon

Clearing of land for development produces the largest amount of sediment to aquatic resources; developed areas can produce 50-100 times more sediment than agricultural areas. U.S. EPA 1993 (in Stanley et al. 2005); Jones and Gordon 2000 (in Stanley et al. 2005).

Increased phosphorus and nitrogen levels in soils and surface runoff; 40 times the amount of nitrogen in agricultural land than forested areas and two times the nitrogen levels of urban areas in Puget Sound. Carpenter et al. 1998 (in Stanley et al. 2005); Ebbert et al. 2000 (in Stanley et al. 2005).

Excessive fertilizer use has led to increased nutrient levels in aquatic environments, causing algal blooms and eutrophication. Caffrey et al. 2007.

Activities within riparian areas have simplified aquatic and riparian habitats. Spence et al. 1996 (in Everest and Reeves 2006).

SECTION I: Introduction/Background

The Marine Riparian Technical Review Workshop (riparian workshop) was held on November 19, 2008 at the University of Washington’s School of Aquatic and Fishery Sciences. The goal of the workshop was to solicit expert scientific opinion to help the state’s Aquatic Habitat Group (AHG) develop management guidelines to protect marine riparian functions. The AHG is a multi-agency panel assembled to provide guidance for local governments updating Shoreline Master Programs and Critical Areas Ordinances to better protect ecological functions, including marine riparian functions. The riparian workshop included a panel of 14 scientists (including three members of the AHG) with expertise in riparian functions and processes. Panelists were asked to help determine how best to apply knowledge about freshwater riparian functions to protect marine riparian functions and processes. Seven specific riparian functions were addressed during the workshop, including:

A. Water Quality  
B. Shade/Microclimate  
C. Large Woody Debris (LWD) recruitment  
D. Litter Fall/Provision of allochthonous* inputs  
E. Fine Sediment Control  
F. Wildlife  
G. Hydrology/Slope Stability

The names, affiliations, and expertise of panelists (including the three members of the AHG who also served as panelists) are included in Appendix A.

The riparian workshop was the second of a three-phase project. Phase I involved a literature review and the development of draft riparian guidance document; Phase II (the riparian workshop) is the focus of these proceedings. Phase III will involve finalizing the guidance document based in part on expert input solicited during Phase II. Although shoreline managers utilize a variety of tools to protect aquatic and riparian ecosystems, this project is focused on providing guidance on establishing appropriate buffers for protection of marine riparian area functions.

In preparation for the workshop, the AHG modified the functional effectiveness curves (also known as riparian function curves) designed and used by FEMAT (1993) to characterize the relationship between buffer width and riparian functions in freshwater environments of the Pacific Northwest (see original curves at end of Appendix A). These regenerated riparian function curves are based on the results of function studies conducted primarily in freshwater systems and are presented as analogs for

* Allochthonous inputs are organic matter brought in from outside a system.
marine riparian areas. The relevance of freshwater riparian functions to marine riparian functions has been recognized and supported in a number of publications (e.g., Adamus et al. 1991; Desbonnet et al. 1994, 1995; NRC 2002; Brennan and Culverwell 2004; Lavelle et al. 2005). The curves plot the relationship between buffer width (X axis) and its relative effectiveness (Y axis) in maintaining or providing a particular function (e.g., pollution abatement/water quality, LWD recruitment, wildlife habitat). These curves are particularly well suited to define tradeoffs between buffer width or size and function loss based on the following assumptions:

1. By virtue of their location, riparian areas mediate important ecological processes and functions that benefit adjacent water bodies (and vice versa).
2. The functional effectiveness of buffers at various widths illustrated by the riparian function curves reflects a generic or typical setting (i.e., a prototypical morphology and physical setting of a relatively undisturbed vegetation community growing adjacent to a water body).

Most studies focus on receiving waters to measure and observe how riparian functions are manifested in the ecosystem, yet many of these ecological functions occur within the riparian area as well. For example, the curve describing LWD recruitment is measured from the middle or edge of the stream, not within the riparian area. For some functions, site potential tree height (SPTH) was used as a proxy for buffer width, whereas other buffer width determinations are provided as simple linear measurements. More details about how the riparian function curves were used to solicit expert opinion during the riparian workshop is included in the following section. Input gathered from panelists during the workshop on the applicability of riparian research to protect marine riparian functions is intended to meet the state’s best available science criteria.

SECTION II: Workshop Objectives and Approach

The four key objectives for the workshop were to:

1. Solicit expert opinion on the applicability (or fit) of using freshwater riparian function curves to protect marine riparian functions.
2. Solicit expert opinion on the uncertainties associated with the application of buffers in different physical or ecological settings (e.g., geomorphology, vegetation type and cover, exposure, etc.).
3. Identify literature that could help inform the development of buffers for marine riparian areas.
4. Identify data gaps, uncertainties, and research needs associated with marine riparian areas.

To achieve these objectives, the workshop was divided into three facilitated sessions as described below.

Session I: Background/context
Panelists were provided with background information on marine riparian protection efforts in the Puget Sound region. This was followed by an overview and summary of scientific information for each of the seven riparian functions addressed in the workshop. Riparian function curves for six of the seven riparian functions (wildlife was not included, see details in section III d) were presented along with underlying science used to generate the curves, providing a context for how applicable the function curves could be for marine settings.

**Session II: Riparian function curve review**

Panelists were asked to review the riparian function curve generated for each riparian function and to respond to three questions:

1. **Does the riparian function curve “fit” (e.g., is it applicable) in marine settings?** The applicability of a particular function curve refers to how well the curve describes the functions of marine riparian areas in a prototypical shoreform/beach type in Puget Sound.

2. **How important is this riparian function in marine settings?** Panelists were asked to provide their opinion on the capacity of undisturbed marine riparian areas to provide each function or process on a scale of 1 (lowest) to 10 (highest). For example, for the hydrology/slope stability function, participants were asked to assign points based on their understanding of marine riparian areas’ ability to protect hydrology and slope stability functions derived from riparian vegetation. This information was used to generate discussion and help the workshop organizers better understand where and why opinion differed among panel members.

3. **How should the curve be modified to better characterize the marine riparian environment?** If the panelists thought a function curve did not accurately describe a relationship, they were asked how the curve should be modified to better describe it. Panelists were asked to provide supporting information for suggested modifications.

**Session III: Additional information (caveats, controlling factors, missing literature, and data gaps):**

For each of the seven functions, panelists were asked:

1. Which controlling factors (e.g., shore form, slope, disturbance, vegetation type, aspect, soils, etc) are most important in determining the specific relationship between buffer width and this function?

2. What additional literature would be informative?

3. What data gaps exist?
SECTION III: Overview of Riparian Functions and Key Findings of Science Panel

A. Water Quality

Overview

The water quality function of riparian areas is well understood and widely documented, although much of the literature is focused on freshwater systems. Riparian vegetation and soils bordering both freshwater and marine systems act in concert to intercept and absorb water; absorb and process nutrients, sediments, and pollutants; store and transmit water; and retain or decompose pollutants (Correll 1997; Wenger 1999; Vigil 2003; Brennan and Culverwell 2004; Hawes and Smith 2005). Vegetation and soils decrease surface and subsurface water velocity and flow, thereby increasing the potential for retention, filtration, and/or transformation of sediments and other contaminants. A number of factors have a strong influence on buffer effectiveness for water quality, including vegetation type and density, topography and slope (i.e., geomorphology), contaminant load, amount of impervious surface, ability to provide sheet flow (as opposed to channelized flow), infiltration/absorption capacity, organic and moisture content of soils, and soil texture (permeability).

Riparian function curve for water quality
The data (Table 1) and graph (Figure 1) below were adapted from Desbonnet et al. (1995) to provide a generalized representation of buffer width recommendations for water quality. It is considered a good synopsis of the findings of several buffer review and synthesis papers, and was one of the few sources of summary data for water quality effectiveness at various buffer widths.
Table 1. Summary data used to produce a generalized curve for effectiveness of vegetated buffers to remove various pollutants at different widths (adapted from Desbonnet et al. 1995). TSS = total suspended sediment. We found no information available on composition of vegetation within the buffer.

Figure 1. Contaminant removal effectiveness of four water quality constituents at various buffer widths (adapted from Desbonnet et al. 1995).
Key science panel findings

Water quality is an important function of marine riparian areas, but relative to the dynamics affecting water quality in Puget Sound at the watershed and landscape scales, many panelists concluded that an undisturbed marine riparian area’s contribution to maintaining water quality is proportional to the upland area. Anthropogenic activities in marine riparian areas undoubtedly include the generation and routing (via water) of pathogens, nutrients, toxics, heat, and fine sediment (above normal background levels) that can affect water quality. However, the marine riparian area is limited in spatial extent; that is, it constitutes a small fraction of the Puget Sound drainage basin. Most contaminants reach Puget Sound via:

1) Streams or drainage networks discharging into the Puget Sound Basin, or pathways that concentrate rainfall and snowmelt from impervious surfaces associated with human residential and commercial development and transportation infrastructure; and

2) Waste water entering Puget Sound from municipal and industrial facilities (i.e. municipal sewage treatment plants and direct discharge from industrial facilities).

Thus, while minimizing impervious surfaces and controlling harmful inputs into surface and groundwater is as important in marine riparian areas on an acre for acre basis as it is across the entire Puget Sound basin, many panelists believed that relative to the larger watersheds that deliver pollutants to Puget Sound, marine riparian areas contribute a small fraction of the ecological function in mitigating water quality impacts at a landscape scale. However, given their proximity to nearshore development and their role in influencing shoreline habitats and species, the panel generally agreed that marine riparian areas do play a role in protecting water quality (i.e., site specific, along marine shorelines) and contribute to the cumulative watershed influences. One aspect of residential development in marine riparian areas not addressed during the workshop included pollution from failing septic systems including bacteria and nutrients.

Panelists generally agreed that the curve in Figure 1 is conceptually valid for water quality issues originating in marine riparian areas.

B. Shade/Microclimate

Overview

Marine riparian areas have unique natural climate control mechanisms that differ from upland areas and which influence both physical and biological conditions at a local scale. Riparian vegetation can intercept solar inputs and help create microclimate conditions (soil and ambient air temperature, moisture, solar radiation, wind, humidity) in both terrestrial and aquatic environments (FEMAT 1993;
Knutson and Naef 1997; May 2003; Parkyn 2004). Forested buffers have an insulating effect, helping to moderate ambient air, soil, and water temperatures, keeping them warmer in the winter and cooler in the summer (Castelle et al. 1992; FEMAT 1993; Osborne and Kovacic 1993; Knutson and Naef 1997; Chen et al. 1999; Wenger 1999; Bavins et al. 2000; Rice 2006; Tonnes 2008).

Riparian function curve for shade
In order to develop a graphic representation of shade effectiveness (Figure 2), the generalized curve from FEMAT (1993) (Appendix D) was used to generate the data needed (Table 2) to create a plot of buffer width effectiveness at varying distances from the edge of a forest stand.

**Key science panel findings**

Panelists unanimously agreed that shade/microclimate is an important marine riparian function. In contrast to freshwater environments, where shade can help moderate stream water temperatures, shade in marine environments was considered less important in moderating water temperature than in moderating temperatures of beach substrates in the supratidal zone and in intertidal zones during low tides, especially during summer months. Panelists noted that while increases in solar radiation due to loss of riparian shade could warm shallow intertidal waters, the effects of this warming have not been quantified. They pointed to studies indicating that riparian vegetation plays an important role in the survival of forage fish spawn (Penttila 2001; Rice 2006) by reducing either heat or desiccation stress. They also noted that solar radiation is an important limiting factor for most rocky intertidal organisms (Ricketts and Calvin 1968; Connell 1972), and that shade may be particularly important for climate-sensitive species. Panelists also noted that ultraviolet radiation is an important consideration because it will persist, even on cloudy days.

Additional panel comments include:
- Overall, vegetation community type is an important consideration for assessing the shade function as some shorelines, even in an undisturbed state, do not support forest community types.
Important factors that influence marine riparian shade include aspect, SPTH, bank morphology, and other site characteristics that affect plant growth.

Loss of overstory trees can increase solar radiation to the patch and to the upper beach – an effect that may persist for decades or even longer.

The continuity of the vegetated community structure over time is an important component of the shade characteristics it provides (as well as other functions) and is influenced by natural processes and disturbances. In the Puget Sound marine environment, where slumping cliffs and erosion are common shoreline characteristics, the shade function depends on a recruitment process. For example, the setback distance of a tree that is 50 feet from the shoreline today will shrink over time as a result of bank erosion, or surface soil creep. This differs from the shade function in freshwater environments, which may be relatively more stable, but is somewhat analogous to a relocation of the stream channel in a floodplain, albeit with somewhat greater predictability because the shoreline only migrates in one direction.

Data gaps

- Limited knowledge exists on survival thresholds for climate-sensitive species, especially in the marine environment.
- Microclimate data are typically derived from upland research. Applying upland climatic data to the marine environment where many buffers are simply one-sided is a large data gap.
- Research is needed on the influence of shade to groundwater (some of which is discharged to beaches via surface flows) on shorelines.

C. Large Woody Debris (LWD) Recruitment and other functions of wood

Overview

The contribution of large woody debris (LWD) into marine environments is considered an important function of marine riparian areas, although the relative proportion of wood delivered from the marine setting compared to river systems is not well documented (Brennan and Culverwell 2004; Tonnes 2008). The role of upland riparian areas in providing LWD in freshwater environments, however, has been very well studied. It is generally believed that LWD provides similar functions in both freshwater and marine systems (Harmon et al. 1986; Sedell et al. 1988; Bilby and Bisson 1998; Hyatt and Naiman 2001; Latterell and Naiman 2007) including:

- Accumulation of organic matter and sediments.
- Habitat structure for periphyton (Coe et al. 2009), invertebrates, fish, and wildlife.
- Bank stability and erosion control.
- Substrate (such as “nurse logs”) for recruitment of plant species.
- Moderation of local benthic temperatures and moisture regimes on beaches.
The source of LWD in streams and rivers is riparian forest growth both adjacent to and upland from the stream channel. Similarly, the natural source of marine LWD (also known as “driftwood”) comes from adjacent marine riparian areas, or is delivered from rivers, streams, and other shoreline areas via marine currents. In recent decades, the volume and quality (wood variety and dimensions) of LWD from natural sources appear to have been reduced due to historic and current logging practices, the conversion of shoreline areas for agriculture and flood control levees, and urbanization (Tonnes 2008). Persistence and residency time of LWD are controlled by decomposition rates of different wood types, size and dimensions of the wood, their ability to become trapped or anchored, and the exposure to hydraulic forces (e.g., river flows, tides, waves, currents).

*Riparian function curve for LWD*

For the LWD riparian function curve (Figure 3), cumulative effectiveness of LWD recruitment data (Table 3) was plotted as a function of potential tree height (based on the FEMAT 1993).

**Table 3.** Approximated data used to create generalized curve (Figure 3) indicating percent of LWD recruitment function occurring within varying distances from the edge of a forest stand (adapted from FEMAT 1993). Note that one SPTH equals 200 feet (61 meters).

Key science panel findings

In general, the science panel agreed that the LWD effectiveness curve is conceptually valid although the proportion of marine LWD entering via shorelines versus river systems is largely unknown. The panel recognized that the quantity and availability of marine LWD is likely to be lower now than historically, particularly in the largest diameter classes, as a result of historic harvest, urbanization, salvage logging, and efforts by the U.S. Army Corps of Engineers to remove floating logs that pose navigation hazards. Wood entering beaches from coastal shorelines may be more stable since this LWD often includes root balls, or may be anchored in the bank, which could reduce its mobility during high tide and storm events. Dan Tonnes discussed his thesis research in Whidbey Basin, where he found that 1.4 percent of the LWD on sediment bluff beaches originated from adjacent unstable bluffs. Additional points raised by the panel included:

- LWD is important for many nearshore organisms that use wood as food and habitat.
- LWD helps stabilize beaches and reduce wave-cut erosion of bluffs.
- The shape of the function curve is primarily based on downhill delivery, within a distance of a single tree height and for more stable and less steep. The shape of the curve would be different under steeper and less stable slope conditions.
D. Litter Fall/Provision of Allochthonous Inputs

Overview

Riparian areas contribute significantly to material creation, cycling, and movement between terrestrial and aquatic systems (Lavelle et al. 2005; Ballinger and Lake 2006). Although the exchange of energy and nutrients between aquatic and terrestrial systems is identified as an important ecological process for maintaining productivity, most studies of these interactions focus on the influence of allochthonous inputs of organic material on stream systems. The contribution of these inputs to marine systems and influence on productivity and other ecological functions is not well understood.

Riparian vegetation provides organic litter that serves as habitat and food for fishes and aquatic invertebrates (Adamus et al. 1991; Vigil 2003; Lavelle et al. 2005;; Ballinger and Lake 2006). Aquatic invertebrates are important components of stream systems and are often used as indicators of stream health (Wenger 1999). Riparian vegetation influences the amount and type of terrestrial invertebrates that fall into aquatic systems which in turn serve as a major food source for freshwater fishes, birds, mammals, reptiles, and amphibians (Romanuk and Levings 2003; Sobocinski 2003). Terrestrial insects are an important food source for many salmonids in streams, and have recently been shown to be a large component of the diet in juvenile salmonids while residing in marine nearshore waters of Puget Sound (Sobocinski 2003; Brennan et al. 2004; Duffy et al. 2005; Fresh et al. 2006; Fresh 2007). In addition, some fish and invertebrates feed directly on vegetative detritus (McClain et al. 1998; King County DNR 2001; Vigil 2003; Lavelle et al. 2005).

Riparian function curve for allochthonous inputs

The FEMAT (1993) “litter fall” buffer effectiveness curve was used to recreate a generalized graphic representation of allochthonous inputs because data required to generate a graph were not available from other sources.

**Figure 4.** Generalized curve indicating percent effectiveness of riparian allochthonous input and litter fall occurring within varying distances from the edge of a forest stand. One site potential tree height is equal to 200ft (61m) (adapted from FEMAT 1993).

**Key science panel findings**

Overall there was a general acceptance that organic nutrient exchange is a relevant function of marine riparian areas and that the conceptual curve is a valid representation of marine allochthonous input functions. In addition, there was a consensus on the following:

- **Energy and nutrient exchange is a multi-dimensional characteristic across the aquatic and terrestrial interface.** For example, litter fall/allochthonous input is not limited to leaves, but includes other matter such as plant stems, insects, and other organic matter.

- **Riparian areas are likely an important area of emergence for insects,** and some flying insects may be introduced to marine waters via wind and stream inputs. Panelists noted that some of the insects found on beaches and in the diet of juvenile salmonids do not fly and are not as likely to become airborne and transported via wind.

- **Nutrient exchange is not simply unidirectional, but bi-directional.** Marine derived nutrients are also transported into the terrestrial environment via multiple pathways including:
  - Atmospheric input via wet or dry deposition, which can occur through fires, intensive farming and agricultural activities, and wind erosion (Lavelle et al. 2005).
  - Lateral transfers of nutrients through water flows, including microalgae and macroalgae washed ashore (Adamus et al. 1991; McLachlan and Brown 2006).
  - Decomposing secondary consumers, such as juvenile Pacific herring, Pacific sand lance, longfin smelt, surf smelt, sole, salmon, seabirds, and marine mammals, also contribute nutrients. For example, in freshwater systems, Pacific salmon nutrients are deposited by predators and scavengers in excreta, or as carcasses and skeletons (Cederholm et al. 1999; Naiman et al. 2002; Drake et al. 2006).

  Secondary consumers can transport nutrients to upland areas, facilitating nutrient and energy exchange between terrestrial and aquatic food webs (Ballinger and Lake 2006). For example, Elliott et al. (2003) examined the relationship between bald eagles and Plainfish Midshipman, a demersal fish and intertidal spawner. Between May and June of 2001, the authors found that eagles consumed about 22,700 ± 3,400 midshipman, representing large transfers of nitrogen into trees, and the potential to enhance community productivity along the shoreline.

The overall relevance of this function curve was ranked in the middle, likely because many panelists did not feel knowledgeable enough to make an informed ranking due to a lack of empirical studies in marine riparian systems.
E. Fine Sediment Control

Overview

One of most studied functions of riparian areas is fine sediment control. Fine sediments enter waterways from a number of terrestrial sources, both natural and anthropogenic. The human-derived fine sediments originate primarily from construction sites, suburban and urban developed areas, forestry and agricultural practices, and unpaved roads that drain into waterways. Sediments become exposed and subject to erosion as a result of vegetation removal, excavation, road wash from unpaved roads, and compaction of soils. Once sediments are suspended in and moved by surface water runoff, they can be delivered to waterways unless they settle out or become trapped.

Excess amounts of sediment, particularly fine sediments, can have numerous deleterious effects on water quality and aquatic biota. The following list briefly summarizes several major effects from anthropogenically-produced sediment (adapted from Wenger 1999):

- Sediment deposited in rivers and streams can reduce habitat for fish and invertebrates.
- Suspended sediment reduces light transmittance, which decreases primary productivity.
- High concentrations of fine suspended sediments cause direct mortality, or impairment (such as suffocation and/or reductions in food supply) for many fish and invertebrates.
- Excess suspended sediments can interfere with filter feeders’ apparatus thus reducing the abundance and diversity of filter-feeding organisms, including mollusks and some arthropods.
- Sediments absorb chemical compounds, serving as a delivery mechanism for contaminants to water bodies.

Riparian buffers composed of dense vegetation can act as a “line of defense” for reducing or eliminating anthropogenic sedimentation of waterways in a number of ways by (adapted from Wenger 1999):

- Displacing sediment-producing activities away from a water body;
- Trapping terrestrial sediments in surface runoff;
- Reducing the velocity of sediment-bearing storm flows, allowing sediments to settle out of water and be deposited on land;
- Creating sheet flow of surface waters, reducing channelization (which can increase conveyance and erosion);
- Stabilizing banks and bluffs, preventing landslides and other erosion;
- Intercepting and absorbing precipitation in the canopy, understory, and ground cover, thereby reducing the amount of water that can displace sediments; and/or
• Contributing LWD, which helps to trap sediments, support vegetation, and reduce erosion from stream flows and waves.

Research on buffer effectiveness has examined both forested buffers (composed of native vegetation) and grass buffers, although results are mixed as to which is most effective at controlling fine sediments. Riparian buffers composed of dense vegetation can reduce the velocity of sediment bearing storm flows, help reduce channelization, and intercept precipitation in the canopy thereby reducing the amount and energy of water that can displace sediments. In addition, composition and density of riparian vegetation (both standing and as LWD) are important elements for controlling surface flows, trapping sediments, and reducing erosion. Riparian soils also play an important role in absorbing water and trapping sediments.

An important factor in determining the sediment removal capabilities of riparian areas is slope. Riparian areas with steeper slopes require wider buffers to provide the same level of sediment removal (similarly with contaminant removal). Capacity is also an important consideration. High levels of sediments can exceed the capacity of riparian areas to trap sediments. If overloaded, riparian effectiveness can be reduced to a point where this function is essentially lost.

*Riparian function curve for fine sediment control*

To illustrate fine sediment control in generalized curves for riparian buffer effectiveness at various widths, the summary data from Desbonnet et al. (1995) (Table 5) were used to generate a scatter plot (Figure 5) and associated curves, similar to the riparian buffer curves developed by FEMAT (1993).

Figure 5. Generalized curve illustrating sediment removal effectiveness at various buffer widths (adapted from Desbonnet et al. 1995).

Key science panel findings

There was general consensus by panelists that the riparian function curve for sediment control is conceptually valid. The panelists discussed the relationship between sediment delivery and land use, the role of sediment, the definition of sediment (e.g., size, class), and the source and function of natural versus unnatural causes of sedimentation. Panelists ranked the relevancy of this function as it relates to other marine riparian functions as low, largely because there is a strong contrast in natural and anthropogenic sediment issues in freshwater and marine systems. Panelists noted that maintaining natural erosion and sediment transport processes are critical to maintaining beaches in Puget Sound.
They also noted that much of the sediment nourishing Puget Sound beaches originates in marine riparian areas, facilitated by natural driving forces (wind and wave action, bluff saturation, leading to slope failures). The panelists felt strongly that it was very important to maintain natural sediment inputs from marine riparian areas into Puget Sound – that perhaps the biggest threat to marine systems from human activity is the reduction of sediment inputs by armoring shorelines and disrupting natural erosion of bluffs. This is in sharp contrast to freshwater systems, where riparian areas are managed to minimize human-induced fine sediment inputs which substantially impact habitat and water quality of freshwater streams. Thus, the panel recognized the need to distinguish between “normative” sedimentation rates in marine riparian areas as opposed to human-induced changes to sediment inputs. Further, while the risks of human induced inputs of fine sediments into marine shorelines have not been as well studied as freshwater systems, the panel recognized marine riparian areas as important for ensuring “normative” sediment processes and reductions of potentially harmful levels of fine sediments from anthropogenic activities.

Additional key comments and questions raised by the science panel are provided under the following topics:

**Definition of Sediment**
- Most reviews of the water quality functions in riparian areas incorporate a discussion of sediment control as part of the discussion of other contaminants. Associating sediment control functions with other water quality functions may help reduce the confusion concerning natural sediment delivery and transport processes versus excessive fine sediment inputs from anthropogenic sources.
- How sediment is defined (e.g., size, class) can change the role and function within the ecosystem as a whole. Perhaps identifying “anthropogenically-derived fines” would help clarify this.
- Sediment delivery is critical to sustaining Puget Sound beaches and is part of the natural watershed process that shapes the shoreline.

**Land Use**
- Land use practices influence the characteristics, timing, and magnitude of sediment input, and can increase annual sediment loads reaching streams by several factors.

**Role of Sediment**
- The role of sediment in nearshore processes of Puget Sound needs to be acknowledged and not confused with controlling fine sediment (and associated contaminant) delivery to marine waters. The compounds that bind to sediment (such as phosphorus) are delivered to the nearshore aquatic environment (where they may play an important ecological role), thus natural levels of sediment delivery should be an important component of riparian management.
F. Wildlife

Overview

In a review of eight separate reports synthesizing much of the literature on riparian functions and buffers, all include a discussion of the importance of riparian areas to wildlife and offer either a range of reported buffer widths, and/or specific buffer recommendations for protection of wildlife habitat. The provision of wildlife habitat is commonly identified as one of the most important functions of riparian areas by meeting important life history requirements such as feeding, breeding, refuge, and migration corridors.

Riparian function curve for wildlife

FEMAT (1993) did not generate a riparian function curve for wildlife. Although a number of other publications describe the importance of riparian areas for supporting wildlife, functional effectiveness data are specific to individual species life history requirements, so it was not possible to generate a function curve. Some researchers have attempted to use physical criteria (plant community, microclimates) as a surrogate for identifying unique riparian habitat attributes for wildlife.

Key science panel findings

Although no riparian function curve for wildlife was available for panel review, there was general consensus that marine riparian areas provide a suite of functions for wildlife as habitat buffers and migration corridors. Some participants pointed out that there are a number of species that would not utilize marine nearshore areas, or cross onto beaches, if a buffer did not exist, which led to a discussion of obligate versus facultative uses. All panel members agreed that marine riparian areas provide a suite of important services for wildlife and this function was rated high across the panel. Discussion on the wildlife function included:

Obligate/Optimal Use Species

- There are few known marine riparian obligate species and it was unclear if the process of identifying obligate species in marine riparian areas had been carried out. It is believed that most wildlife in these areas are generalized in their use and preference, although few studies have focused on this set of questions for marine riparian areas. The unique aspect about the marine riparian environment is that it supports a number of important functions and processes that create and maintain wildlife habitat. Diversity was mentioned frequently with regard to riparian areas; many wildlife species are generalists in their use of ecotones, so increased local species diversity may or may not lead to high regional diversity. Heightened local diversity occurs because structural diversity and vegetation are linked closely with the aquatic system. Larger buffers
would benefit bigger animals with wider ranges, and are important for wildlife sensitive to human disturbances. See Marzluff (2005), Sax and Gaines (2003), and Scott and Helfman (2001).

- Invasive species within riparian areas need to be considered as they may reduce buffer effectiveness. Buffers can harbor nuisance species and any pathogens that are transported along with their introduction, which is a cause for concern with respect to local wildlife and human populations.

Additional Key Comments:
- It may be helpful to provide more information on the functions of ecotones in the guidance document (e.g., define and provide information on multiple functions of ecotones).
- Need to consider obligate versus facultative use species in the buffer. For example, some shorebird species may be obligate users of the marine riparian zone during migration periods.
- Address seasonal variability as it relates to wildlife usage;
- Need to consider supralittoral (i.e. the splash/spray zone above spring high tide line, not submerged by water) use by plovers, seals, otters, deer, and other animals.
- Buffer areas could disrupt or enhance migratory pathways, depending on the species life history requirements and habits.
- Functional connectivity between habitats does not always have to be continuous; some animals can leap-frog areas.
- Some structural elements may need to be considered for specific wildlife needs (may vary with beach and/or buffer type).
- Wildlife may have important roles, through selective feedings and deposition of nutrients, in shaping the structure and productivity of marine riparian areas (Naiman and Rogers 1997).

G. Hydrology/Slope Stability

Overview

Substantial literature exists on the role of vegetation in controlling hydraulic processes and increasing slope stability. Much of this literature addresses the impacts (such as sedimentation, siltation, and excessive flow volumes) of logging, agriculture, urbanization, and other practices to streams and wetlands. A significant portion of the literature on impacts has little to do with maintaining or protecting ecological functions of riparian or aquatic systems, but rather focuses on how these impacts affect human infrastructure. Regardless of the system (freshwater or marine), or the focus of the research and assessment reports (ecological or social implications), the general consensus is that vegetation can play an important role in controlling hydrologic processes and slope stability in the following ways (adapted from Griggs et al. 1992: IN Macdonald and Witek 1994):
- **Interception**: Foliage and plant litter absorb the energy of precipitation, reducing direct impacts on soil.
- **Restraint**: Root systems bind soil particles and blocks of soils, and filter sediment out of runoff.
- **Retardation**: Plants and litter increase surface roughness, and reduce runoff volume and velocity, reducing channelization.
- **Infiltration**: roots and plant litter help maintain soil porosity and permeability.
- **Transpiration**: plants absorb moisture, delaying the onset of soil saturation and surface runoff.

In addition, the influences of woody plants on mass movement may include:

- **Root Reinforcement** – Roots mechanically reinforce soil by transferring shear stresses in the soil to tensile resistance in the roots.
- **Soil Moisture Depletion** – Interception of raindrops by foliage as well as evapotranspiration limit buildup of soil moisture.
- **Buttressing and Arching** – Tree trunks can act as buttress piles or arch abutments in a slope, counteracting shear stresses.
- **Surcharge** – The weight of vegetation on a slope may exert a destabilizing down slope stress and a stress component perpendicular to the slope that increases resistance to sliding.
- **Root wedging** – Roots invade cracks and fissures in soil or rock that could add restraint stability or cause local instability by wedging action.
- **Wind throw** – Strong winds exert an overturning movement on trees causing blow down (usually of aged, diseased, or undermined trees) that disturb slope soils.

**Riparian function curve for hydrology and slope stability**

No data could be found plotting the functional effectiveness of the hydrology/slope stability function, so data were generated following the model provided by Griggs et al. (1992) (IN Macdonald and Witek 1994) were used to create Table 6 and Figure 6. This study addresses setbacks on bluffs and other unstable slopes to protect against property loss.

Figure 6. Construction setbacks for different bluff heights at various levels of stability, where geologic stability for 50 years cannot be demonstrated (after Griggs et al. 1992).
Key science panel findings

All participants agreed that the hydrology/slope stability graphic is applicable in the marine environment. Panelists discussed the importance of hydrology, geomorphology, soil type, and vegetation type in supporting slope stability functions in Puget Sound, in addition to the human safety concerns about slope stability in the region.

Geomorphology

- Landforms and geology can be more important here than buffer width. For example, in the San Juan Islands, there can be a 45° slope on basalt form that can be very stable.
- Consider geomorphic shore form (e.g., geologic legacy, landscape position, density, slope, etc.). Use of Shipman (2008) geomorphic classification system may be useful.

Soil and Vegetation

- Soils and vegetation play important roles in slope stability and hydrology.
- The relationship of riparian vegetation and slope stability is very specific to hydrologic and geologic conditions. It is important to consider flow paths; for example, stability may be associated more with altered upland drainage patterns or precipitation patterns. Therefore, this relationship may be site-specific.
- Need to consider the role of vegetation on the slope itself versus above the slope, which would yield different functions. The relative importance of vegetation at each location, given site-specific conditions and methods of protection need to be determined. Similar to the discussion of “sediment” above, management should allow for normative rates of LWD recruitment and erosion to provide sediments and wood to beaches.
- Buffer width versus landform may be the most important factor. For example, steeper slopes, particularly those with underlying geologic instability, require wider buffers.
- Need to maintain normative rates of sediment delivery by using setbacks and buffers – should avoid interfering with natural processes.
- Upslope alterations are large contributing factors to slope instability.
- Home protection and public hazard considerations are likely to garner public support for buffers.
- Riparian areas can increase slope stability (through root structure) and increase water interception and absorption. Protecting natural rates of sediment delivery and protecting processes and functions of nearshore ecosystems may be achieved by establishing and maintaining adequate riparian buffers.
SECTION IV: Summary and Conclusions

The purpose of this workshop was to solicit expert opinion on how best to apply riparian science to protect marine riparian functions and processes with a particular emphasis on buffers. The science panel included fourteen scientists with expertise related to riparian ecosystems. Panelists were asked for input on a variety of questions related to seven specific riparian functions and/or processes.

In general, panelists agreed that findings from studies of freshwater riparian areas are transferable to marine riparian areas, although some processes and functions are unique to marine riparian areas.

A summary of panelist responses to the key questions follows (note: questions were asked for each of seven riparian functions).

1. Is there general agreement that this function applies in the marine environment? On a scale of 1-10 (low to high), what is the relative importance of this particular function in the marine environment?

General consensus was reached that each of the seven functions reviewed during the workshop applies in both freshwater and marine riparian environments, although their relative importance varied. For example, three functions (LWD, litter fall, and hydrology) emerged as having higher relative importance to marine environments, based on a subjective ranking process. Many panelists noted that marine riparian science would be greatly improved with additional research. It was also generally agreed these areas should be viewed and managed holistically to address multiple processes and functions at small and large spatial and temporal scales.

Water Quality – The panel agreed that while water quality is an important function of marine riparian areas overall, the relative contribution of these areas is minor at a larger scale compared to the freshwater inputs from the Puget Sound drainage basin as a whole. However, water quality functions provided by marine riparian areas may be very important, especially at a site specific level, depending upon land use practices and the integrity of the riparian area.

Shade/Microclimate – According to the panel, shade is of medium relative importance to marine riparian areas in Puget Sound relative to water temperatures in the marine environment, which was judged to be less sensitive to solar inputs than waters in freshwater systems. However, shade has been shown to play a role in survival of upper intertidal organisms in Puget Sound. Additional research is needed to fully understand its role. Erosion and tree removal within and outside the riparian buffer can disrupt the shade function in the marine environment. In addition, the limited knowledge on the survival thresholds for climate-sensitive species in the marine nearshore environment is a major data gap.
**LWD Recruitment** – LWD in the marine nearshore provides important functions but it was unclear how much of that wood comes from marine riparian areas versus rivers. LWD is known to supply nutrients, stabilize beaches and banks, reduce wave erosion, enhance establishment and growth of vegetation, and provide refuge, nesting and foraging habitat for a variety of species. There is an overall general lack of information specific to the marine environment, but sources of LWD to beaches include freshwater riparian material, logging activity, and marine riparian areas. Recruitment of marine LWD requires buffers that allow for natural erosion and recruitment over extended time periods as banks and bluffs recede.

**Litter Fall/Provision of Allochthonous Inputs** – These inputs are relevant to both marine and freshwater environments. Terrestrial source nutrients have been shown to be important to the nearshore ecosystem, and some studies have determined that riparian areas serve as emergence habitat for fish prey and support a number of trophic levels in the nearshore food web. Nutrient and energy exchange is not unidirectional and marine derived nutrients find their way to terrestrial environments. Some panelists noted that the contribution of allochthonous inputs to and their influence on productivity in marine systems is a data gap.

**Fine Sediment Control/Delivery** – This process is important in both marine and freshwater systems. Sediment delivery to the Puget Sound via river systems and eroding marine bluffs (convergence zones) is critical to beach forming processes. Fine sediments originating from anthropogenic sources need to be distinguished from natural sources and background levels. Riparian areas can help control harmful levels of fine sediment and associated contaminant delivery to the aquatic environment while allowing natural processes to continue.

**Wildlife** – Marine riparian areas provide a suite of habitat functions for wildlife including feeding, breeding, and migration corridors. Some panelists pointed out that there are a number of species that would not cross into the nearshore area if a marine riparian buffer did not exist. Few studies have focused on wildlife utilization of marine riparian areas, but much of what has been studied about the life history requirements in other areas would apply to those species that occur in these areas. Some species may be highly adapted to marine riparian areas and could be considered obligate species, although survey data are lacking.

**Hydrology and Slope Stability** – Vegetation can play an important role in controlling runoff, maintaining slope stability, and maintaining normative rates of erosion. From this perspective, one function of a riparian area is protecting people from landslides. The safety factors provided by buffers may resonate with people more directly if the argument is framed in terms of the need for normative rates of erosion and sediment delivery to beaches along with protection of human structures.
2. Does the FEMAT-style curve adapted for this function “fit” for the marine environment? (Yes or No)

Nearly every panelist agreed that all six of the FEMAT-style curves adapted for riparian processes and functions (a wildlife functional effectiveness graph was not provided) were a reasonable “fit” or conceptually valid for the marine environment, notwithstanding site and scale controlling factors. Several exceptions and caveats were included, such as the LWD function (every panelist felt that the curve’s “fit” would vary at a site specific scale); and the shade function (participants pointed to many factors that needed to be considered, including aspect and temporal/spatial variability.

3. Which controlling factors are most important in determining the specific relationship between buffer width and function (e.g., shore form, slope, vegetation type, aspect, soils)?

Responses to this question are summarized in Table 7 below. The discussion of these topics was very limited due to time constraints.

Table 7. Controlling factors for riparian buffer functions.

Parking Lot Ideas

Throughout the workshop, panelists brought up ideas, issues, concerns, and questions. A number of these topics and considerations were outside the scope of the workshop but were noted as “Parking Lot” issues. They fell into two main topic areas: buffer management and research gaps and needs, and have been grouped by these two categories below.

Guidance on Buffer Management

- Many uncertainties exist in managing marine riparian areas. Using a precautionary approach and adaptively managing these areas is important.

- Management of marine riparian areas must consider a time element. Like many other ecological elements, the processes and functions of marine riparian areas evolve over extended time periods, which need to be considered for developing appropriate management actions. For example, since plants and plant communities (extent, age since last disturbance, composition) are important determinants of riparian functions, managers need to consider the time it takes for large trees to grow and plant communities to become established and maintained through time. Similarly, the time it takes to reestablish following a disturbance event (natural or anthropogenic) should be incorporated into the management strategy (e.g., for protection, enhancement, restoration, recreation).

- Management of marine riparian areas must consider multiple spatial scales. Connectivity is an important characteristic of riparian areas for maintaining ecological functions. Fragmentation and narrowing of buffers can have larger-scale effects. Because shoreline development and permitting typically occur on a site-by-site basis, current management does not account for cumulative and large-scale impacts. In addition, bluffs may continue to erode over time, sea levels will rise and existing buffers will likely become narrower as a result of human or natural disturbance, thereby providing reduced functions. This should be a management consideration for creating sustainable processes and functions.

- In addition to ecological functions, riparian areas have important social, cultural, economic, and recreational values and these should be important management consideration.

- Riparian buffers need to be recognized as being important for human safety in addition to their ecological importance. A large portion of Puget Sound shorelines is naturally eroding, which potentially threatens human infrastructure and safety. The effects of climate change are likely to increase erosion rates and threaten existing infrastructure.

- Sediment (including mass wasting) is important for maintaining beaches in Puget Sound and should not be confused with fine “anthropogenic” sediments that could have adverse environmental effects. One of the key functions of riparian areas is pollution abatement (e.g., trapping fine sediments, treatment of contaminants associated with fine sediments, absorption and treatment of water-borne contaminants). Natural sedimentation and transport processes should be maintained, at normative rates, while also ensuring that riparian functions are protected.
The term “large wood” has not been precisely defined within the nearshore setting. “Small wood” (i.e. under 1 m long) has been found to moderate beach temperatures and support richer communities of macroinvertebrates.

Invasive and nuisance species can have a profound effect on riparian functions. Many invasive and nuisance species are well-adapted to disturbance and once established, may alter natural processes and functions, and/or may prevent native species from reestablishing.

Marine riparian buffers should not be the sole mechanism by which the marine nearshore ecosystems are protected.

Resiliency of vegetation in marine riparian areas is a function of patch size. As vegetation patches become smaller (thinner) and more isolated by human development, they are more likely to experience disturbances that can change structure and function of that plant community. Isolated patches of relatively undisturbed vegetation may be more susceptible to wind-throw, or invasion of nonnative species, such as English ivy. Further, these patches may become isolated to the point where they suffer from a lack of recruitment of new propagules. They can also be eliminated altogether as a consequence of bluff retreat.

**Research Needs and Data Gaps**

- Link riparian processes and functions to a geomorphic classification for Puget Sound. A geomorphic classification (e.g., Shipman 2008) may be helpful in developing a riparian classification scheme and may also be informative for identifying important marine riparian functions and processes.
- Determine a standard for describing buffer widths. Some investigators have used site potential tree height (SPTH) for determining buffer widths.
- The influence of groundwater on trees and vegetation in the riparian zone.
- Relative contribution of litter fall/allochthonous inputs from the riparian zone versus rivers and other outside areas.
- Value of litter fall/allochthonous inputs and relative food web energetic contribution to the riparian system.
- Identification of priority pollutants in the Puget Sound nearshore system. The panelists noted the need to understand the role of septic systems as likely primary pollutant sources in marine riparian areas; in freshwater systems, septic pollution has been shown to affect fish community structure (Moore et al. 2003).
- Identification of optimal use and obligate species in marine riparian areas.
- Classification of the intensity, frequency, and conditions that could give rise to massive slope stability failures in Puget Sound.
- Vegetation dynamics and the effects on riparian function in areas surrounded by human developed lands.
- Riparian condition related to volumes/timing and types of terrestrial insects delivered to nearshore settings.
- The geomorphic functions of driftwood along various Puget Sound shoreline types.
